## Abstract

Debt is sustainable at a competitive equilibrium due solely to the reputation of debtors for repayment; that is, even absent collateral or legal sanctions available to creditors. In the presence of uninsurable risks or in an asset market that is incomplete, when the rate of interest (net of growth) is recurrently negative, self-insurance is more costly than borrowing, and repayments on loans are enforced by the implicit threat of loss of risk-sharing advantages of debt contracts. Private debt credibly circulates as a form of inside money and, in general, is not valued as a speculative bubble; it is distinct from outside money. Competitive equilibria with self-enforcing debt exist under a suitable hypothesis of gains from trade.

**Keywords:** Rate of interest, self-enforcing debt, reputational debt, incomplete markets, competitive equilibrium

# 1 Introduction

Debt is a fact of life in market economies and it plays a determining role in the allocation of resources over time and under uncertainty. The result in [Bulow and Rogoff \(1989a\)](#) presents a conundrum to be explained, rather to be explained away. If creditors have no legal rights whatsoever, debtors are able to borrow only if they can maintain a reputation for repayment, as pointed out by [Eaton and Gersovitz \(1981\)](#). However, if the loss of reputation cannot prevent debtors from continuing to save in financial markets after default, and they maintain access to cash-in-advance insurance contracts, then default on debt obligations, eventually, becomes profitable. Indeed, debtors that have reached the upper bound on liabilities may prefer to declare bankruptcy and to divert saved repayments to acquire cash-in-advance contracts. This is feasible and, as shown by [Bulow and Rogoff \(1989a\)](#), generates higher utility as long as the upper bound on debt is strictly positive. Creditors anticipate debtors' incentives to default and provide no loans at all.

In contrast to this traditional view, we here show that, in the presence of uninsurable risks, debt is sustainable even if not secured by collateral or by sanctions against debtors upon default. In fact, creditors can rely solely on the benefits debtors derive from the ability to borrow and, as a consequence, their reputation for repayment. We identify the implicit enforcement mechanism, and we show the existence of a competitive equilibrium with unsecured debt. At equilibrium, debt credibly circulates in the economy and reflects fairly the value of future repayments.

It might seem that profitability of default would fail when the asset market is incomplete, due to the limited protection against risk available upon default. However, the absence of insurance opportunities provides, by itself, no stronger incentives to debt repayment, as it affects the borrower before as well as after default. In fact, [Auclet and Rognlie \(2016\)](#) showed that the claim of [Bulow and Rogoff \(1989a\)](#) extends to incomplete markets when the interest rate is constant. In general, with time-varying interest rate, we proved in [Bloise, Polemarchakis, and Vailakis \(2017\)](#) that default is unavoidable when the greatest valuation of the debtor's endowment is finite, whereas debt can be credibly sustained by the reputation for repayment if only the least valuation is finite.<sup>1</sup> Our analysis in this paper establishes that conditions for sustainable debt are not exceptional and, rather, emerge naturally when the prices of securities are determined by market clearing at a competitive equilibrium.

[Hellwig and Lorenzoni \(2009\)](#) showed that debt is sustainable in economies with a complete asset market when the rate of interest is determined endogenously to clear markets. Their insight and contribution rely on an equivalence between speculative bubbles and self-enforcing debt, a variation of the bubble equivalence theorem in [Kocherlakota \(2008\)](#). At a competitive equilibrium with

---

<sup>1</sup>Disparities in the valuation of future incomes are unavoidable under incomplete markets, as these contingent claims are not traded and, hence, are not priced by the market. The absence of arbitrage opportunities only imposes an upper bound and a lower bound on present values. See, for instance, [LeRoy and Werner \(2014\)](#) on this general principle of finance.

a speculative bubble, an asset with no fundamental value allows for intertemporal consumption smoothing, exactly as money does in the monetary economy in [Bewley \(1980, 1983\)](#). At a competitive equilibrium with self-enforcing debt, instead, each individual issues private debt and this is valued in the market as a speculative bubble. In other terms, the privileges of issuing the speculative bubble are assigned to individuals as opposed to be embodied in an asset in positive net supply. In fact, incentives to default disappear because individuals are allowed to exactly roll-over outstanding debt period by period and, as a consequence, no effective repayment is enforced.<sup>2</sup> Differently from a situation with complete markets, we show that debt cannot be rolled over and, as such, does not circulate as a speculative bubble. This reveals a substantive failure of the claim in [Bulow and Rogoff \(1989a\)](#).

How can debt be self-enforcing? Consider a situation in which the value of a claim to the entire future income of a debtor is finite, as in [Bulow and Rogoff \(1989a\)](#). This provides an upper bound on the debtor's repayment capacity (the natural debt limit) and rules out the debt roll-over regime that occurs in [Hellwig and Lorenzoni \(2009\)](#). Upon default, no further debt can be issued and the debtor shall have to rely on self-insurance. When markets are complete, saved repayments can be invested in specific portfolios of securities that replicate equivalent risk-sharing advantages of debt contracts. As an interest accrues from these investments, saved repayments more than compensate for the cost of self-insurance. When markets are incomplete, however, contingent claims for an equivalent insurance may not be tradable and, without issuing debt, risk-sharing contracts can only be acquired at a higher cost. Therefore, the loss due to the increased cost of self-insurance may well exceed the gain from default and this provides an implicit incentive to debt repayment.

When a risk-free bond is the only available security, for instance, consumption smoothing can only be attained through trade in uncontingent claims. When rates of interest remain recurrently negative for a long phase with some probability (though somehow positive on average), the cost of self-insurance grows prohibitively high. This is so because saving depreciates at a negative rate of interest. When debt can be issued, instead, insurance obtains at a sensible lower cost, as outstanding debt can be refinanced at a negative rate of interest. Hence, debt is a superior instrument and repayments are implicitly enforced by the threat of loosing borrowing privileges.

We show that, under incomplete markets, debt roll-over in general fails at a competitive equilibrium with self-enforcing debt. The argument is not evident, and it requires us to extend a method based on the dominant root (Perron-Frobenius) approach.<sup>3</sup> The long-term rate of interest is only ambiguously iden-

---

<sup>2</sup>In the working paper version, [Bulow and Rogoff \(1989a\)](#) explicitly ruled out such *Ponzi-type reputational contracts* by the assumption of a finite market value of the entire income stream of the debtor.

<sup>3</sup>For complete markets, [Alvarez and Jermann \(2005\)](#) and [Hansen and Scheinkman \(2009\)](#) follow a similar approach. Their purpose is to derive a lower bound for the volatility of the permanent component of asset pricing kernels. Our purpose instead is to provide necessary conditions at a competitive equilibrium with self-enforcing debt for individuals to exactly

tified under incomplete markets and dominant roots provide bounds on its estimates. When the long-term rate of interest is unambiguously positive, in a roll-over regime, debt explodes. On the contrary, it vanishes over time, along with trade, when the long-term rate of interest is unambiguously negative. Neither case is consistent with a competitive equilibrium in which trade persists. When long-term rate of interest is never positive and occasionally negative, debt is sometimes refinanced at a discount and, in a roll-over regime, additional debt is in fact sustainable at equilibrium, a contradiction. As a result, a necessary condition for persistent debt roll-over is that the long-term rate of interest be unambiguously zero. This imposes excessively severe limitations, as rate of interest will need to adjust upwards and downwards to clear markets.

We also establish the existence of a competitive equilibrium with self-enforcing debt. Our approach exploits the dominant root to show that trade occurs at equilibrium. We perturb the economy by introducing a legal sanction: upon default a small fraction of the endowment is confiscated. This is sufficient to enforce repayment of any debt not exceeding the present value of confiscated resources. As a result, borrowing and lending occur in the perturbed economy and, at a competitive equilibrium, a claim into each debtor's entire future income is finite. We then progressively remove the auxiliary sanction and consider the limit with no confiscation. This is a competitive equilibrium of the original economy and trade occurs under a suitable *gains from trade* hypothesis: the implicit value of a claim into each debtor's entire income is (robustly) infinite at autarky. Indeed, as this claim has a finite value in the perturbed economy, autarky cannot be the limit as the perturbation is removed. The dominant root is used to convert this intuition into an accurate argument.

We complement our analysis with an exploration of incentives to default for exogenously given Markov pricing kernels. This is the privileged framework of the sovereign debt literature, where the pricing kernel is interpreted as the valuation of foreign investors who provide credit under full commitment.<sup>4</sup> Under incomplete markets, when no future borrowing is the punishment for default, we show that debt may be sustainable when foreign investors are risk-averse and risk premia vary along the business cycle.<sup>5</sup> When the pricing kernel is sufficiently volatile, the foreign investors' value of a claim into the borrower's entire future income is finite (high implied rates of interest), but the value of the claim becomes infinite when evaluated using other legitimate state prices

---

roll over existing debt period by period. The analysis of the dominant root under incomplete markets was developed in [Bloise, Polemarchakis, and Vailakis \(2017\)](#) for Markov pricing kernels with strictly positive transitions. An extension is necessary because the Markov property generally fails at a competitive equilibrium with self-enforcing debt when some risks are uninsurable.

<sup>4</sup>This framework is inspired by [Eaton and Gersovitz \(1981\)](#) and extensively studied, among others, by [Aguiar and Amador \(2014\)](#), [Aulert and Rognlie \(2016\)](#) and [Wright \(2013\)](#). [Eaton and Fernandez \(1995\)](#) and [Panizza, Sturzenegger, and Zettelmeyer \(2009\)](#) provide comprehensive reviews of the traditional literature.

<sup>5</sup>Recent quantitative work on sovereign default risk, in [Arellano \(2008\)](#), [Arellano and Ramanarayanan \(2012\)](#) and [Hatchondo, Martinez, and Sosa-Padilla \(2016\)](#), moves away from the traditional risk-neutral pricing to provide a better understanding of risk premia, the term-structure of interest rates and movements along the business cycle.

(low implied rates of interest). On one hand, high implied rates of interest preclude debt roll-over or, according to [Bulow and Rogoff \(1989a\)](#), Ponzi-type reputational contracts. On the other hand, low implied rates of interest render borrowing more appealing and saving after default more costly. When these effects trade off, default is not profitable and debt is sustained by the mere reputation for repayment.

We briefly relate our contribution to previous studies in two separate branches of literature: sovereign debt and money. The objection of [Bulow and Rogoff \(1989a\)](#) to the reputation argument for repayment posed a powerful challenge to the notion that the threat of exclusion from credit markets, by itself, supports sovereign borrowing. As a consequence, the literature evolved in three distinct directions. In a first line of research, as in [Bulow and Rogoff \(1989b\)](#), debt repayment is sustained by direct punishments, interpreted as the outcome of interferences with the debtor's transactions upon default. A second line of research, as in [Kletzer and Wright \(2000\)](#), develops the idea that sovereigns repay because they are worried about the repercussions of default, for instance, for the credit market. In a third line of research, incentives to repay sovereign debt arise from possible broader adverse effects on a borrower's reputation, as in [Cole and Kehoe \(1998\)](#). All these previous studies take their cue from the critique of [Bulow and Rogoff \(1989a\)](#) and explore alternative, and more effective, mechanisms for debt enforcement. We, instead, rely solely on the debtor's reputation for repayment and show the limited validity of the claim of [Bulow and Rogoff \(1989a\)](#) with residual uninsurable risks.

The absence of debt roll-over provides a relevant insight into the distinction between inside money and outside money. When markets are complete, [Hellwig and Lorenzoni \(2009\)](#) establish an equivalence between an equilibrium with self-enforcing debt (inside money) and an equilibrium with unbacked public debt (outside money). We show that this coincidence in general fails under incomplete markets. With uninsurable risks, an equilibrium with self-enforcing debt is distinct from a [Bewley \(1980, 1983\)](#) monetary equilibrium. Self-enforcing debt is backed by the credible promise of future repayments, as the implicit mechanism guarantees that outstanding claims are honored. In particular, the value of a claim into the debtor's future income (the natural debt limit) is finite, as in any competitive equilibrium with full commitment. In the monetary economy of [Bewley \(1980, 1983\)](#) the (unmodelled) absence of enforcement mechanisms prevents credit markets from operating and an unbacked currency plays a relevant social role in helping individuals smooth their consumption over time. Money only circulates as a speculative bubble and requires an infinite present value of future income. A relevant implication of our argument is that self-enforcing debt is consistent with empirical tests ruling out speculative bubbles and ascertaining dynamic efficiency of the economy, as in [Abel, Mankiw, Summers, and Zeckhauser \(1989\)](#).

A more counter-intuitive equivalence between money and credit is found in [Gu, Mattesini, and Wright \(2016\)](#) under special assumptions on trading arrangements. Indeed, they show that changes in credit conditions are neutral because real balances respond endogenously so as to conserve total liquidity,

and welfare.<sup>6</sup> On the contrary, our analysis reveals that credit and money are different sources of liquidity under incomplete markets or, else, that their equivalence is an artifact of the hypothesis of complete markets. In fact, in general, a competitive equilibrium with credit (inside money) differs from a competitive equilibrium with (outside) money. Furthermore, neutrality fails even under the most favorable scenario, in which money is undominated as an asset and is not demanded because of liquidity preference.

Our argument has indirect implications for monetary policy. Indeed, we show that the market is able to provide endogenous sources of liquidity. Because this endogenous form of liquidity only relies on reputation and does not require any legal enforcement, regulation may not be effective and self-enforcing debt may interfere with the objectives of monetary policy. For instance, when a counter-cyclical policy requires a restrictive intervention, the inside money channel may instead provide an expansion of liquidity. Furthermore, the inside supply of liquidity may be more vulnerable to autonomous revisions of expectations and elude the stabilizing action of monetary policy.

We organize the paper as follows: We begin with the presentation of a simple example in §2. In §3 we describe the economy and define a competitive equilibrium with self-enforcing debt. As debt sustainability depends on long-term rates of interest, in §4 we develop our dominant root approach. In §5 we employ the dominant root method to identify a necessary condition for debt roll-over that, when markets are incomplete, can only be satisfied in singular situations. In §6 we establish the existence of an equilibrium with trade and effective sustainable debt. In §7 we further explore the incentives to debt repayment for a given Markov pricing kernel. Finally, we present some concluding remarks. All proofs we collect in Appendix A; in Appendices B, C and D we provide additional material.

## 2 A motivating example

How can debt be sustainable when it is not secured by collateral or legal sanctions? A simple example provides the underlying intuition and elucidates the enforcing mechanism. When the rate of interest is recurrently negative, self-insurance may be too costly, and debt may provide insurance services more efficiently than other instruments. Thus, debt may be implicitly secured by the threat of diminished insurance opportunities upon default, contrary to what [Bulow and Rogoff \(1989a\)](#) claimed. In the example, these conditions are determined *ad hoc* for heuristic purposes. As our general analysis illustrates, however, they will naturally emerge at a competitive equilibrium under incomplete mar-

---

<sup>6</sup>The analysis in [Gu, Mattesini, and Wright \(2016\)](#) is broader, though limited to a specific setting, because nominal interest is positive and money is held for liquidity purposes even though dominated as a credit instrument. In the absence of additional transaction constraints, instead, dominated money would not be valued in our set up or that in [Hellwig and Lorenzoni \(2009\)](#).

ket.<sup>7</sup>

At each period, there are two states of nature,  $S = \{l, h\}$ , occurring with equal probability. A risk-free (discount) bond is the only security, and its price is either  $q_h > 1$  or  $q_l < 1$ . An individual can trade the risk-free bond over time, issuing debt when needed, under no commitment for repayment. As in [Bulow and Rogoff \(1989a\)](#), denial of future credit is the only punishment for default.

Preferences on consumption streams are given by a conventional discounted expected utility; that is,

$$U((c_t)_{t=0}^{\infty}) = \mathbb{E}_0 \sum_{t=0}^{\infty} \delta^t c_t,$$

where, to simplify computations, the borrower is risk-neutral, and  $\delta$  in  $(0, 1)$  is the discount factor. The endowment is constant,  $e > 0$ . We assume that the discount factor  $\delta$  lies in  $(0, q_l)$ . This ensures that the individual is sufficiently impatient and will never save after default. Autarky is, thus, the reservation utility.

We consider a simple consumption plan in which outstanding debt remains constant over time. This is not a roll-over regime because repayments occur and, though the rate of interest is recurrently positive along some path, debt is not exploding. The outstanding stock of debt is  $d > 0$ , while consumption is, depending on the current price of the bond,

$$c_s = e + (q_s - 1)d > 0.$$

The feature of this plan is that, when interest is positive ( $q_l < 1$ ), some resources are devoted to debt service; when the rate of interest is negative ( $q_h > 1$ ), debt can be refinanced at no cost and excess resources are diverted to consumption. The stock of debt remains unaltered over time. Is default profitable under these conditions?

Because of our simplifying assumptions, the accounting is straightforward. The expected discounted utility conditional on no default is

$$\begin{aligned} U_s(d) &= e + (q_s - 1)d \\ &+ \left( \frac{\delta}{1 - \delta} \right) \left( e + \left( \frac{q_h - 1}{2} \right) d + \left( \frac{q_l - 1}{2} \right) d \right). \end{aligned}$$

As saving is never optimal, autarky is the expected discounted utility upon default; that is,

$$U_s(0) = e + \left( \frac{\delta}{1 - \delta} \right) e.$$

---

<sup>7</sup>For the sake of simplicity, we consider a risk-neutral borrower, though risk-aversion could be easily accommodated at the cost of increased complexity in calculations. In the spirit of the arbitrage argument in [Bulow and Rogoff \(1989a\)](#), we exhibit a plan for the borrower independently of optimality and equilibrium conditions. However, considering an *ad hoc* lender as we explain below, we could embed the example in our competitive equilibrium ([§3.4](#)) with explicit not-too-tight debt limits (precisely,  $g_l = d$  and  $g_h = d + (q_h - q_l)d$ ). In particular, the plan would be optimal for the borrower subject to these solvency constraints.

As a matter of fact, default is unprofitable if and only if

$$\left(\frac{\delta}{1-\delta}\right)\left(\frac{q_h-1}{2}\right) \geq (1-q_l) + \left(\frac{\delta}{1-\delta}\right)\left(\frac{1-q_l}{2}\right).$$

The right hand-side is the value of saved repayments, whereas the left hand-side is the value of excess consumption afforded by refinancing debt at a negative rate of interest. The condition is certainly satisfied for fixed  $q_h > 1$  provided that  $q_l < 1$  is sufficiently close to unity. Thus, debt is sustainable.

The example clarifies why the arbitrage argument of [Bulow and Rogoff \(1989a\)](#) fails under incomplete markets. When debt is not rolled over, repayments are necessarily enforced beginning from some contingency. By defaulting, the borrower saves on these repayments at the cost of no further debt in the future. When markets are complete, saved repayments can be used to pay up-front for the same insurance as without default and, as a result, denial of future credit bears no effective cost. This arbitrage is precluded in the example because markets are incomplete. Indeed, the rate of interest may remain negative for a long phase. Before default, the borrower benefits from refinancing outstanding debt. After default, the upfront value of a positive net consumption can be arbitrarily large, because a negative rate of interest accrues on savings. Thus, default entails a large cost, whereas the gain from saved repayments may be relatively small (and, in fact, vanishes when  $q_l = 1$ ).

Debt cannot be rolled over in this example. In fact, it is bounded by the least present value of future endowment (the natural debt limit); that is,

$$d \leq \sum_{t=0}^{\infty} q_l^t e = \left(\frac{1}{1-q_l}\right) e.$$

This rules out Ponzi games and enforces recurrent repayments. In [Hellwig and Lorenzoni \(2009\)](#), instead, borrowers simply roll over their debt obligations and no debt repayment is enforced. This situation occurs only under implausibly restrictive conditions at a competitive equilibrium when markets are incomplete (see §5).

In the sovereign debt literature, beginning with [Eaton and Gersovitz \(1981\)](#), the pricing kernel is determined by the valuation of foreign investors whose commitment is enforced by the legal system. When markets are complete, this induces a finite value of the sovereign's future income and debt is unsustainable, as established by [Bulow and Rogoff \(1989a\)](#). Under incomplete markets, instead, foreign investors' valuation may be finite and, yet, debt may be sustainable. To accommodate this in our example, we can assume that the typical foreign lender is risk-averse and risk premium is time-varying because of the international business cycle. The price of the bond is determined by marginal rates of substitution; that is,

$$q_h = \delta^* \left( \mu_{hh} \frac{u'(c_h^*)}{u'(c_h^*)} + \mu_{hl} \frac{u'(c_l^*)}{u'(c_h^*)} \right), \quad (2.1)$$

$$q_l = \delta^* \left( \mu_{lh} \frac{u'(c_h^*)}{u'(c_l^*)} + \mu_{ll} \frac{u'(c_l^*)}{u'(c_l^*)} \right), \quad (2.2)$$

where  $(c_l^*, c_h^*)$  are the foreign investors' consumption levels,  $\delta^*$  in  $(0, 1)$  is their discount factor, and  $\mu$  denotes the transition probabilities. By discounting, the present value of sovereign's endowment is certainly finite when computed at state prices corresponding to discounted marginal utilities. Hence, when markets are incomplete, the valuation of foreign investors may be finite even though the borrower has no incentive to default.<sup>8</sup>

Along the lines of this simple example, in Appendix B, we consider a competitive economy with two risk-neutral individuals in which gains from trade arise because of differences in marginal utilities.<sup>9</sup> Depending on idiosyncratic shocks, each individual will be issuing debt, recovering it and providing credit to the other individual. As in the previous example, debt cannot be rolled over because the natural debt limit is finite. If debt were to exceed the natural limit, its value would be growing unboundedly over time. As the debt of an individual is balanced by the credit of the other individual, this situation would necessarily imply an over-accumulation of assets for the creditor and thus a violation of the transversality condition.

### 3 The economy

#### 3.1 Fundamentals

The economy extends over an infinite horizon,  $\mathbb{T} = \{0, 1, 2, 3, \dots\}$ . Uncertainty is represented by a probability space,  $(\Omega, \mathcal{F}, \mu)$  and a filtration  $(\mathcal{F}_t)_{t \in \mathbb{T}}$  of  $\sigma$ -algebras. To simplify, and to avoid issues of integrability, we assume that, for every  $t$  in  $\mathbb{T}$ ,  $\mathcal{F}_t$  is a  $\sigma$ -algebra generated by a *finite* partition of  $\Omega$ . Given a state of nature  $\omega$  in  $\Omega$ , at every period  $t$  in  $\mathbb{T}$ ,  $\mu(\mathcal{F}_t(\omega)) > 0$ , where  $\mathcal{F}_t(\omega) = \cap \{E_t \in \mathcal{F}_t : \omega \in E_t\}$  describes the (publicly) available information. Throughout the analysis, we refer to any of such primitive events as a *contingency*. In the equivalent event-tree representation of uncertainty, a contingency corresponds to a date-event or a node.

Let  $L$  be the linear space of all adapted processes with values in  $\mathbb{R}$ , *i.e.*, of all maps  $f : \mathbb{T} \times \Omega \rightarrow \mathbb{R}$  such that, for every  $t$  in  $\mathbb{T}$ ,  $f_t : \Omega \rightarrow \mathbb{R}$  is  $\mathcal{F}_t$ -measurable, and let  $L_t$  be the space of such  $\mathcal{F}_t$ -measurable maps. An adapted process  $f$  in  $L$  is positive (respectively, strictly positive, uniformly positive) whenever, at every  $t$  in  $\mathbb{T}$ ,  $f_t(\omega) \geq 0$  (respectively,  $f_t(\omega) > 0$ ,  $f_t(\omega) \geq \epsilon > 0$ ), for all  $\omega$  in  $\Omega$ . As usual,  $L^+$  denotes the positive cone of  $L$ .

---

<sup>8</sup>A more speculative way of explaining this property is that, under incomplete markets, the hypothesis of high implied rates of interest (that is, a finite present value of the endowment) may hold true at some state prices and fail at some other state prices. Foreign investors' marginal valuation corresponds to state prices for which implied rates of interest are high. This does not exclude that the value is infinite for some other state prices.

<sup>9</sup>The example is rather convoluted. In general, it is hard to construct simple competitive equilibria under incomplete markets. When risk is uninsured, shocks alter the distribution of wealth and prices need to vary in order to guarantee market clearing (see, for instance, [Kehoe and Levine \(2001, Proposition 7\)](#)). Furthermore, when debt is self-enforcing, the endogenous value of default has to be determined explicitly, adding an independent complication.

There is a finite set,  $I$ , of individuals. For every individual  $i$  in  $I$ , the *consumption space*  $C^i$  is  $L^+$ , the positive cone of  $L$ , and the *endowment* is  $e^i$  in  $C^i$ .

**Assumption 3.1** (Endowment). The endowment  $e^i$  in  $C^i$  is uniformly positive and uniformly bounded with respect to the aggregate; that is, for some sufficiently large  $\epsilon_u > 0$  and some sufficiently small  $\epsilon_l > 0$ , at every  $t$  in  $\mathbb{T}$ ,

$$\epsilon_l e_t \leq e_t^i \leq \epsilon_u e_t,$$

where the strictly positive process  $e$  in  $L^+$  is the aggregate endowment.

To simplify, we impose restrictive assumptions on preferences, though this is unnecessary for most of our analysis. Every individual is characterized by a canonical expected discounted utility. Preferences over the consumption space  $C^i$  are induced, at every period  $t$  in  $\mathbb{T}$ , by

$$U_t^i(c^i) = \mathbb{E}_t \sum_{s \in \mathbb{T}} \delta^s u^i(c_{t+s}^i),$$

where  $\delta$  in  $(0, 1)$  is the common discount factor. A strong Inada condition helps the arguments by ensuring strictly positive consumption.

**Assumption 3.2** (Utility). Per-period utility  $u^i : \mathbb{R}_{++} \rightarrow \mathbb{R}$  is smooth, smoothly strictly increasing and smoothly strictly concave. Furthermore, it is bounded from above and satisfies the strong Inada condition

$$\lim_{c^i \rightarrow 0} u^i(c^i) = -\infty.$$

A consumption plan  $c^i$  in  $C^i$  is *individually rational* if, at every  $t$  in  $\mathbb{T}$ ,

$$U_t^i(c^i) \geq U_t^i(e^i).$$

Notice that individual rationality is imposed at all contingencies and not only *ex ante*. An allocation  $c$  in  $C$  specifies a consumption plan  $c^i$  in  $C^i$  for every individual  $i$  in  $I$ . It is *feasible* if, at every  $t$  in  $\mathbb{T}$ ,

$$\sum_{i \in I} c_t^i \leq \sum_{i \in I} e_t^i.$$

The space of individually rational and feasible allocations is denoted by  $C(e)$ . A simple lemma clarifies that individually rational consumption will be uniformly positive due to the strong Inada condition.

**Lemma 3.1** (Lower bound on consumption). *When the aggregate endowment  $e$  in  $L^+$  is uniformly positive, every individually rational consumption plan  $c^i$  in  $C^i$  is also uniformly positive.*

### 3.2 Competitive markets

Short-term securities are sequentially traded in competitive markets. Available assets may not allow for all contingent transfers; that is, markets may be sequentially incomplete. As specific features play no direct role in our analysis, we opt for a parsimonious primitive description of the set of securities via pricing and payoff functionals. Our framework encompasses sequentially complete markets as a particular case. In some of our analysis, we restrict attention to economies in which only the risk-free bond is available.

A finite set,  $J$ , of securities is traded over time in the asset market. At every period  $t$  in  $\mathbb{T}$ , security  $j$  in  $J$  is described by a market price  $q_t^j$  in  $L_t$  and a possibly contingent payoff  $R_{t,t+1}^j$  in  $L_{t+1}$  at the following period. A trading plan,  $z$  in  $Z$ , is an adapted process in  $L^J$ , where  $z_t$  in  $Z_t$  is the portfolio of securities held in period  $t$  in  $\mathbb{T}$ . Portfolios are priced by the linear functional  $q_t : Z_t \rightarrow L_t$  and yield a contingent payoff according to the linear functional  $R_{t,t+1} : Z_t \rightarrow L_{t+1}$ . Notice that, when the risk-free bond is the only asset, the portfolio  $z_t$  is a simple random variable in  $L_t$ , and the payoff functional takes the form  $R_{t,t+1}(z_t) = z_t$ .

At every contingency, each individual is subject to a budget constraint,

$$q_t(z_t^i) + c_t^i \leq e_t^i + v_t^i, \quad (3.1)$$

where wealth  $v^i$  in  $V^i$  (the space of adapted processes in  $L$ ) evolves according to

$$v_{t+1}^i = R_{t,t+1}(z_t^i).$$

An additional, solvency constraint requires that

$$-g_{t+1}^i \leq R_{t,t+1}(z_t^i), \quad (3.2)$$

where  $g^i$  in  $G^i$  is the adapted process of debt limits restricting trade in securities. Mandatory saving is ruled out, so we assume that debt limits are positive (that is, they belong to  $L^+$ ).

A solvency constraint of the form (3.2) was initially introduced by [Zhang \(1997\)](#) and later adopted by [Alvarez and Jermann \(2000\)](#). It is an indirect portfolio restriction: an individual may hold a portfolio implying a promise to delivery at some future contingency; that is,  $R_{t,t+1}(z_t^i) < 0$ , only if this liability does not exceed the threshold given by debt limits. Notice that, because any portfolio with positive payoffs is still allowed ( $g^i$  lies in  $L^+$ ), solvency constraints do not interfere with the traditional no arbitrage theorem and, hence, redundant securities are priced under parity. Finally, when a risk-free bond is the only security, the solvency constraint (3.2) takes the simpler form

$$-g_{t+1}^i \leq z_t^i.$$

Beginning from any contingency in period  $t$  in  $\mathbb{T}$ , an individual maximizes expected discounted utility subject to budget and solvency constraints. Conditional on no default, the indirect utility is denoted by  $J_t^i(v_t^i, g^i)$ . It depends

on the available initial wealth,  $v_t^i$  in  $V_t^i$ , inherited from the past, and on the entire future adapted process for debt limits  $g^i$  in  $G^i$ , as well as on the process of security prices  $q$  in  $Q$ . We need to ensure that, as commitment is limited, default is never profitable.

### 3.3 Not-too-tight debt limits

In line with [Bulow and Rogoff \(1989a\)](#) and [Hellwig and Lorenzoni \(2009\)](#), default entails the seizure of all assets and the loss of access to future borrowing opportunities. When only a risk-free bond is available, this implies that the bond cannot be sold short anymore. When multiple securities are available, a defaulter is allowed to form portfolios as long as they do not involve any future liabilities; that is, obligations to deliver at some future contingency. Thus, all insurance contracts remain available after default provided they imply positive contingent payoffs.<sup>10</sup> Debt limits are set so that no debtor has an incentive to default and no lender can profit from extending credit beyond a borrower's debt limit.

Formally, as in [Alvarez and Jermann \(2000\)](#) and [Hellwig and Lorenzoni \(2009\)](#), debt limits that are *not too tight* allow for the maximum amount of credit that is compatible with repayment at all contingencies. This requires that, for every individual  $i$  in  $I$ , at every  $t$  in  $\mathbb{T}$ ,

$$J_t^i(-g_t^i, g^i) = J_t^i(0, 0). \quad (3.3)$$

The left hand-side is the value of market participation, beginning with the maximum sustainable debt, whereas the right hand-side is the value of default. Indeed, upon default, all assets are cleared ( $\hat{v}_t^i = 0$ ) and no borrowing is permitted in the future ( $\hat{g}^i = 0$ ). Debt limits are not-too-tight if the individual is indifferent between repayment and default.

### 3.4 Competitive equilibrium

Given the initial distribution of wealth,  $v_0$  in  $V_0$ , a *competitive equilibrium with self-enforcing debt* consists of an allocation  $c$  in  $C$ , a price  $q$  in  $Q$ , trading plans  $z$  in  $Z$  and debt limits  $g$  in  $G$  such that the following conditions are satisfied.

- (a) For every individual  $i$  in  $I$ , given initial claims  $v_0^i$  in  $V_0^i$ , the plan  $(c^i, z^i)$  in  $C^i \times Z^i$  is optimal subject to budget constraints [\(3.1\)](#) and solvency constraints [\(3.2\)](#) at debt limits  $g^i$  in  $G^i$ .

---

<sup>10</sup>When some securities cannot be traded after default, or portfolios are further restricted by no short sale constraints, debt is implicitly secured by the cost of restricted access to some financial instruments, as in [Pesendorfer \(1992\)](#). The admission of any trade that involves no future liabilities is more in the spirit of *cash-in-advance* contracts after default; that is, upfront payments for future contingent deliveries.

(b) Commodity and financial markets clear; that is, at every  $t$  in  $\mathbb{T}$ ,

$$\sum_{i \in I} c_t^i = \sum_{i \in I} e_t^i, \text{ and } \sum_{i \in I} z_t^i = 0.$$

(c) For every individual  $i$  in  $I$ , debt limits  $g^i$  in  $G^i$  satisfy the not-too-tight condition (3.3).

This concept of equilibrium follows exactly [Alvarez and Jermann \(2000\)](#), except that the default punishment is the denial of future credit, instead of complete autarky. When markets are complete, it coincides with the equilibrium with self-enforcing debt studied by [Hellwig and Lorenzoni \(2009\)](#).

## 4 Dominant root

Whether debt is sustainable or not depends on long-term rates of interest (net of growth). As proved by [Bulow and Rogoff \(1989a\)](#), when the rate of interest is positive, default will necessarily occur at some contingency, unless debt is rolled over. Debt would be exploding under a roll-over regime, a situation which is inconsistent with equilibrium, because some other individual would be over-accumulating assets and violating the necessary transversality condition. When the rate of interest is negative, on the other side, debt would be imploding over time, so as to disappear in the long-run. Debt is sustainable only if rates of interest are neither persistently negative nor persistently positive in the long-run. This clear intuition is obscured by the fact that the rate of interest will in general vary over time and across states. Thus, to identify exact conditions, we need to develop a simple theory of the long-term rate of interest.

We introduce an elementary, though subtle, dominant root approach in order to estimate the long-term rate of interest. Because markets are incomplete, these estimates identify an upper bound and a lower bound only. Indeed, long-term bonds are not traded and their payoffs may not be replicable by available securities. As the pricing kernel is in general not Markovian at a competitive equilibrium, no restriction is imposed apart from the fact that securities are priced under no arbitrage. To avoid uninteresting situations, we also suppose that, at every  $t$  in  $\mathbb{T}$ , there is a portfolio  $z_t^*$  in  $Z_t$  such that  $R_{t,t+1}(z_t^*) > 0$  at all contingencies. This is certainly satisfied when the risk-free bond is available.

As in the traditional no arbitrage theory, in [LeRoy and Werner \(2014\)](#), for example, at every  $t$  in  $\mathbb{T}$ , we define the *valuation functional*  $\Pi_t : L_{t+1} \rightarrow L_t$  as

$$\Pi_t(b_{t+1}) = \inf_{z_t \in Z_t} q_t(z_t),$$

subject to

$$b_{t+1} \leq R_{t,t+1}(z_t).$$

This gives the minimum expenditure to meet future obligations, conditional on available securities. Formally, this valuation defines a monotone sublinear

functional.<sup>11</sup>

Ideally, long-term rates of interest would be estimated by the dominant eigenvalue of the valuation operator, as in the Perron-Frobenius Theorem, and this approach is developed in Appendix D for Markov pricing kernels with strictly positive transitions. A general theory under our weak assumptions is not available, and we need to provide an alternative suitable method. To ensure existence, we define dominant roots as accumulation points and this will suffice for our purposes.

As dominant roots shall capture the long-term rate of interest net of the rate of growth of the economy, we first need to consider a suitable space. Let  $L(e)$  stand for all adapted processes that are bounded by some expansion of  $e$  in  $L^+$ ; that is,

$$L(e) = \{x \in L : |x| \leq \lambda e \text{ for some } \lambda > 0\}.$$

This space contains all streams of contingent payoffs that do not grow unboundedly relative to the aggregate endowment. The *upper dominant root*  $\rho(q)$  in  $\mathbb{R}_+$  is the greatest  $\rho$  in  $\mathbb{R}_+$  such that, for some non-zero  $b$  in  $L^+(e)$ , at every  $t$  in  $\mathbb{T}$ ,

$$\rho b_t \leq \Pi_t(b_{t+1}).$$

Similarly, the *lower dominant root*  $\gamma(q)$  in  $\mathbb{R}_+$  is the greatest  $\gamma$  in  $\mathbb{R}_+$  such that, for some non-zero  $b$  in  $L^+(e)$ , at every  $t$  in  $\mathbb{T}$ ,

$$\gamma b_t \leq -\Pi_t(-b_{t+1}).$$

Notice that, as the valuation functional is monotone sublinear,

$$\gamma(q) \leq \rho(q).$$

Upper and lower dominant roots are well-defined (admitting positive infinity as a value), though we cannot in general establish the existence of their associated eigen-processes. Neither we can provide an operational criterion for their computation under general pricing kernels. Heuristically, the upper dominant root estimates the minimum growth rate of savings, whereas the lower dominant root corresponds to the maximum growth rate of debt, both relative to the aggregate endowment. We intuitively discuss some properties of dominant roots and relegate a formal analysis of simple irreducible Markov pricing kernels to Appendix D.

When only a risk-free bond is traded, dominant roots admit an elementary characterization for simple Markov pricing kernels with strictly positive transitions: they correspond, respectively, to the highest and to the lowest price of the

---

<sup>11</sup>Notice that, under no arbitrage, the cost-minimizing portfolio exists; that is, there is a portfolio  $z_t$  in  $Z_t$  such that

$$\Pi_t(b_{t+1}) = q_t(z_t)$$

and

$$b_{t+1} \leq R_{t,t+1}(z_t).$$

Indeed, remember that all  $\sigma$ -algebras are generated by finite partitions and, hence, the valuation functional only involves a collection of cost-minimization programs in finitely dimensional spaces.

bond or, equivalently, to the lowest and to the highest rate of interest. When multiple securities are traded, this link becomes less transparent: for instance, the upper dominant root may be less than unity ( $\rho < 1$ ) even though the rate of interest is recurrently negative over time and thus the greatest price of the risk-free bond is greater than unity. When markets are incomplete, in general, the upper and the lower dominant root will be distinct.

Dominant roots act, in a way, as discount factors for future contingent claims. When markets are incomplete, the present value of future claims is ambiguous, because they cannot be replicated using available securities. The greatest valuation is finite when  $\rho < 1$ , whereas a finite least valuation occurs provided that  $\gamma < 1$ .<sup>12</sup> This bears a relevant implication for debt sustainability. Indeed, the analysis in [Bloise, Polemarchakis, and Vailakis \(2017\)](#) assumes an exogenously given pricing kernel satisfying  $\rho < 1$  and shows that debt is unsustainable. Differently, in this paper debt is sustainable because  $\rho \geq 1$  at a competitive equilibrium. When  $\gamma < 1$ , the least present value of the endowment is finite and this restricts the debt capacity of an individual: any debt exceeding this natural debt limit cannot be honored. When  $\gamma \geq 1$ , instead, any arbitrary amount of debt can be repaid in finite time. Clearly, under limited commitment, default may occur even when debt repayment is feasible.

## 5 Debt roll-over

The dominant root approach permits us to provide a better understanding of conditions under which debt is sustainable at a competitive equilibrium. Under complete markets, [Hellwig and Lorenzoni \(2009\)](#) prove that self-enforcing debt limits necessarily allow borrowers to exactly roll over existing debt; that is, to exactly refinance outstanding obligations by issuing new claims. In fact, equilibrium allocations with self-enforcing private debt are equivalent to allocations that are sustained by unbacked public debt subject to no borrowing. Repayments are not required and private debt circulates as a speculative bubble. We show that, under incomplete markets, this roll-over property fails, in general, when the rate of interest is time-varying. Debt repayments are enforced by a proper reputational mechanism, contrary to the claim of [Bulow and Rogoff \(1989a\)](#).

We consider a competitive equilibrium with non-vanishing debt.<sup>13</sup> We say that debt limits allow for *persistent debt roll-over* whenever, for some individual  $i$  in  $I$ , there is an adapted process  $b^i \leq g^i$  in the interior of  $L^+(e)$  such that

---

<sup>12</sup>As in Claim [D.3](#) in Appendix [D](#), the greatest and the least valuations of the endowment (if they exist) are given by (the minimal) processes  $f^\rho$  and  $f^\gamma$  in  $L^+$  satisfying, respectively, at every  $t$  in  $\mathbb{T}$ ,

$$f_t^\rho = e_t + \Pi_t(f_{t+1}^\rho) \text{ and } f_t^\gamma = e_t - \Pi_t(-f_{t+1}^\gamma).$$

<sup>13</sup>When debt is unsecured, expectations of future deterioration of solvency conditions may be self-fulfilling, and trade may vanish in the long-run. Debt is sustainable, but it disappears over time, inducing no trade in the limit. We neglect competitive equilibria of this nature and focus on those in which trade and, hence, debt occur persistently.

$b_0^i = g_0^i$  and, at every  $t$  in  $\mathbb{T}$ ,

$$\Pi_t(-b_{t+1}^i) = -b_t^i.$$

This condition guarantees that, beginning from the initial period, any debt level not exceeding the threshold  $g_0^i$  in  $L_0^+$  can be perpetually refinanced by issuing further debt subject to solvency constraints.<sup>14</sup> Over time the individual can repay an amount  $b_t^i$  in  $L_t^+$  of outstanding debt by issuing additional debt up to levels  $b_{t+1}^i$  in  $L_{t+1}^+$  (see footnote 11). Furthermore, debt roll-over is persistent because the adapted process  $b^i$  belongs to the interior of  $L^+(e)$  and, hence, the amount of debt that can be refinanced does not vanish along any path relative to the aggregate endowment. An example clarifies our definition and the role of the component  $b^i$  in  $L^+(e)$  distinguished from debt limits  $g^i$  in  $G^i$ .

**Example 5.1** (Debt roll-over). Suppose that uncertainty is governed by a Markov process on the state space  $S = \{l, h\}$  and that the risk-free bond is the only asset. Also, assume that the price of the risk-free bond is constantly  $q = 1$ , irrespectively of the Markov state  $s$  in  $S$ . Finally, the aggregate endowment is constant. Debt limits are  $g_h > 0$  and  $g_l > 0$ , with  $g_h > g_l$ . In such a situation, debt roll-over occurs for  $(b_l, b_h) = (g_l, g_h)$ . Notice that, however, the amount  $g_h > 0$  of debt in state  $h$  in  $S$  cannot be rolled over, because solvency constraint would be violated in a future state  $l$  in  $S$ .

Our purpose is to verify under which conditions persistent debt roll-over occurs at a competitive equilibrium. In a stationary economy, the intuition is provided by a simple situation in which the risk-free bond is the only security and its price persistently fluctuates between an upper bound  $\rho > 0$  and a lower bound  $\gamma > 0$ . Along a path on which the price of the bond is constantly  $\gamma > 0$ , in a roll-over regime, debt evolves according to

$$\gamma b_{t+1} = b_t.$$

The path would be exploding when  $\gamma < 1$ , and imploding when  $\gamma > 1$ . Neither case is consistent with persistent debt roll-over. Hence,  $\gamma = 1$ . In such a condition, any plan under no borrowing could be replicated along with the permitted debt roll-over, because debt can always be refinanced at a non-positive rate of interest. Supposing that  $\rho > 1$ , the cost of refinancing the debt would be occasionally lower, yielding additional consumption with respect to the no borrowing regime, a contradiction. Hence,  $\rho = 1$ . In other terms, persistent roll-over occurs only if the rate of interest is constantly zero.

**Proposition 5.1** (Roll-over property). *Persistent debt roll-over occurs at a competitive equilibrium only if*

$$\rho(q) = \gamma(q) = 1. \tag{5.1}$$

---

<sup>14</sup>The initial period is used only for narrative convenience. When debt roll-over occurs from some other period, all our arguments apply to the equilibrium beginning from a future contingency.

Necessity of condition (5.1) reveals that persistent debt roll-over is a fragile property. Indeed, under incomplete markets, upper and lower dominant root will in general be distinct when the pricing kernel involves some volatility and, so, condition (5.1) will fail. We discuss this fragility in a *bounded* economy subject to *aggregate uncertainty* in which *only* a risk-free bond is traded.

Notice that, when persistent roll-over occurs at equilibrium, there is an adapted process  $b$  in the interior of  $L^+(e)$  such that, at every  $t$  in  $\mathbb{T}$ ,

$$b_t = q_t b_{t+1},$$

where  $q$  in  $L^+$  is the price of the risk-free bond.<sup>15</sup> For a bounded economy, this implies that the long-term rate of interest is zero along any path; that is,

$$\lim_{n \rightarrow \infty} \sqrt[n]{\prod_{k=0}^{n-1} q_{t+k}} = 1. \quad (5.2)$$

Thus, debt roll-over imposes severe restrictions at a competitive equilibrium with aggregate uncertainty: the rate of interest will require downward or upward adjustments during phases of prosperity or recession, and this flexibility is precluded by the necessary condition (5.2). We first explain this heuristically and then exhibit explicit conditions on primitives. These conditions are sufficient to exclude debt roll-over at equilibrium, but far from necessary.

During phases of prosperity, individuals will have a tendency to accumulate assets for precautionary motives, because recessions are expected in the future. Markets will clear only if these savings are balanced by a corresponding supply of bonds. To provide incentives to borrowing, the rate of interest will need to go through downward adjustments and, under some conditions, will be recurrently negative. More formally, notice that first-order conditions require, at every  $t$  in  $\mathbb{T}$ , that

$$q_t \geq \max_{i \in I} \delta \mathbb{E}_t \frac{\nabla u(c_{t+1}^i)}{\nabla u(c_t^i)}.$$

Thus, under prudence, that is, marginal utility is weakly convex,

$$q_t \geq \max_{i \in I} \delta \frac{\nabla u(\mathbb{E}_t c_{t+1}^i)}{\nabla u(c_t^i)}.$$

When output declines with positive probability, expected consumption will necessarily decrease for some individual and, when individuals are sufficiently patient,

$$q_t \geq \max_{i \in I} \delta \frac{\nabla u(\mathbb{E}_t c_{t+1}^i)}{\nabla u(c_t^i)} > 1.$$

Along a path of persistent prosperity, the rate of interest shall be recurrently negative, which contradicts condition (5.2).

---

<sup>15</sup>This property is the established condition (A.3) in the proof of Proposition 5.1.

**Example 5.2** (Aggregate uncertainty). To identify simple assumptions on fundamentals, consider an economy in which shocks to the aggregate endowment are identically and independently distributed. And suppose that all individuals have constant relative risk-aversion,  $\sigma > 0$ , over a relevant range of consumption levels. Let  $(c_s^i)_{i \in I}$  in  $\mathbb{R}_+^I$  and  $(c_{\hat{s}}^i)_{i \in I}$  in  $\mathbb{R}_+^I$  be, respectively, the distribution of consumptions in current state  $s$  in  $S$  and the distribution of consumptions in future state  $\hat{s}$  in  $S$ . Restriction (5.2) is necessarily violated (Claim A.1) when

$$\sum_{\hat{s} \in S} \mu_{\hat{s}} e_{\hat{s}} < \delta^{\frac{1}{\sigma}} e_s, \quad (5.3)$$

where  $e$  in  $\mathbb{R}_+^S$  denotes the aggregate endowment. This condition is certainly satisfied when individuals are sufficiently patient for an appropriate choice of the current state. On the other hand, in order to have trade at equilibrium with self-enforcing debt (Proposition 6.1), the sufficient condition is

$$\min_{s \in S} \max_{i \in I} \delta \left( \frac{e_s^i}{\sum_{\hat{s} \in S} \mu_{\hat{s}} e_{\hat{s}}^i} \right)^\sigma > 1. \quad (5.4)$$

Both restrictions (5.3) and (5.4) can be robustly fulfilled: debt is valued at equilibrium and cannot be rolled-over.

If roll-over is infeasible, how can unsecured debt be sustained by a truly reputational mechanism? Debt is used to reduce the volatility of consumption when adverse shocks occur. However, as repayment is enforced eventually, the benefit for consumption smoothing will be exhausted at some contingency and default will become profitable. What mechanism prevents default? As initially suggested in [Bloise, Polemarchakis, and Vailakis \(2017\)](#), default bears the implicit cost of reduced insurance opportunities. Upon default no further debt can be issued and future insurance will require up-front payments or, using the terminology of [Bulow and Rogoff \(1989a\)](#), cash-in-advance contracts. When markets are complete, repayments saved upon default can be invested to provide resources to cover future up-front insurance costs. This, in general, requires access to portfolios of securities with suitable contingent payoffs. When markets are incomplete, such portfolios are only fortuitously available and the cost of providing insurance raises, overcoming the gain accruing from saved debt repayment. We shall provide, later, additional intuition in a partial equilibrium framework (§7)

## 6 Existence

We show that, under a suitable gains to trade hypothesis, a competitive equilibrium with self-enforcing debt exists. Private debt is issued as an insurance device against income fluctuations and it trustworthily circulates as the only store of value in the economy. In general, as argued in our previous discussion (§5), debt is sustained by a proper reputational mechanism: default is

unprofitable, because self-insurance is too costly, and outstanding claims are honored. This situation is distinct from a competitive equilibrium in which outside money is valued as a mere speculative bubble, as in Bewley (1980, 1983)), and it is more properly associated with a form of inside money.

We provide a proof of existence when *only a risk-free bond is traded* in an economy where intrinsic uncertainty is governed by a Markov process on the finite space  $S$  with *strictly positive* transitions  $\Pi : S \rightarrow \Delta(S)$ . Individual endowments oscillate according to this Markov process and, hence, all fundamentals are measurable with respect to the finite Markov state space  $S$ . This, in particular, implies that the economy cannot grow or decline over time; that is, the aggregate endowment  $e$  in  $L^+$  is bounded. In general, at a competitive equilibrium, prices would be affected by the distribution of wealth, as well as possibly by future expectations, and would not be measurable with respect to the Markov state space  $S$ . Consequently, we cannot impose any Markov restriction on the pricing kernel.

The major difficulty in establishing existence follows from the fact that no trade is always a competitive equilibrium. This resembles the essential property of fiat money: when money is the only store of value and it is not valued in the market, it will not be demanded, because it bears no intrinsic value, and no intertemporal trade will occur; similarly, when all lenders expect that debtors will default, they are not willing to provide credit and no intertemporal trade will occur. We overcome this obstacle by introducing an approach that, we believe, is novel. Namely, we construct a perturbed economy in which debt is implicitly backed by a share of the private endowment. Trade occurs in this perturbed economy and, as the pledgeable share of the endowment vanishes, debt becomes purely self-enforcing. The dominant root plays an essential role in ensuring that trade persists in the limit.

We construct an auxiliary economy in which, upon default, a fraction  $\epsilon$  in  $(0, 1)$  of the endowment is confiscated and no further borrowing is allowed. This is the economy  $\mathcal{E}^\epsilon$ , whereas the original economy is denoted by  $\mathcal{E}^0$ . A competitive equilibrium exists in the perturbed economy  $\mathcal{E}^\epsilon$ .<sup>16</sup> Debt is still unsecured, because confiscated resources are not diverted to satisfy creditors. However, confiscation makes default unprofitable at any level of debt that can be repaid using a fraction  $\epsilon$  in  $(0, 1)$  of the endowment; that is, not exceeding the least present value of confiscable resources. Indeed, why should a debtor default, and loose a fraction of the endowment, when the debt can be repaid using this fraction? The relevant implication is that, at any equilibrium of the perturbed economy, the *least* present value of the endowment is finite, irrespectively of the share of confiscable resources.

**Lemma 6.1** (Finitely valued endowment). *In any competitive equilibrium of the perturbed economy  $\mathcal{E}^\epsilon$ , there is an adapted process  $f^\epsilon$  in  $L^+(e)$  such that, at*

---

<sup>16</sup>Even for the perturbed economy, we cannot rely on any established theorem in the literature, because of the self-enforcing condition. We present our analysis in Appendix C. To establish existence, we truncate the economy by arbitrarily imposing default in the future and progressively remove this further restriction going to the limit.

every  $t$  in  $\mathbb{T}$ ,

$$f_t^\epsilon = e_t - \Pi_t^\epsilon (-f_{t+1}^\epsilon),$$

where  $e$  in  $L^+$  is the aggregate endowment.<sup>17</sup>

As confiscable resources vanish, the equilibrium allocation cannot converge uniformly to autarky when gains from trade are available. To identify these situations precisely, we construct an implicit pricing at autarky by setting, at every  $t$  in  $\mathbb{T}$ ,

$$q_t^0 = \max_{i \in I} \delta \mathbb{E}_t \frac{\nabla u^i (e_{t+1}^i)}{\nabla u^i (e_t^i)}.$$

The *gains from trade hypothesis* is that  $\gamma(q^0) > 1$ . At a competitive equilibrium of the perturbed economy, instead,  $\gamma(q^\epsilon) < 1$ , because the endowment would not be finitely valued otherwise, and a reversal cannot occur under uniform convergence. Hence, autarky cannot be an accumulation point.

In overlapping generations economies, a similar argument is used to establish the existence of a monetary equilibrium; see [Aiyagari and Peled \(1991\)](#) and, recently, [Barbie and Hillebrand \(2017\)](#): competitive equilibrium is Pareto efficient in the perturbed economy, whereas autarky is not; as a result, a sequence of perturbed equilibria cannot converge to no trade uniformly. The main difference is that monetary equilibria, as well as perturbed equilibria, are Pareto efficient in those economies, whereas they in general fail efficiency in our economy, as well as in the monetary economy in [Bewley \(1980, 1983\)](#). The role of the dominant root is to identify directions of efficiency that are achieved at a perturbed equilibrium and preserved in the limit. In an economy with *outside* assets, this issue is discussed by [Bloise and Citanna \(2016\)](#). We here identify distinguished conditions when only *inside* assets are traded and use them to ensure the existence of an equilibrium with trade.

For simple Markov processes with strictly positive transitions, the gains from trade hypothesis requires that  $q_t^0 > 1$  uniformly. In such a situation, a hypothetical planner can improve upon autarky by means of a simple scheme of transfers: in every period  $t$  in  $\mathbb{T}$ , a small amount  $\eta > 0$  is taken from any individual  $i$  in  $I$  with marginal rate of substitution equal to  $q_t^0$  and distributed to some other individual; in the following period, the donor is compensated with an uncontingent transfer  $\eta > 0$ ; expected utility increases because the compensation is valued more at the margin; that is,  $q_t^0 > 1$ ; this chain of transfers can be continued indefinitely. In this interpretation, the gains from trade hypothesis guarantees a sort of time irreducibility of the economy: the transfer scheme will never be interrupted as a potential donor will always be available. Private debt is valued at equilibrium because it allows individuals to exploit these welfare gains. On the contrary, in general, it will not be valued when similar welfare gains are not available.

---

<sup>17</sup>The above formula recursively computes the least present value of the aggregate endowment (see Appendix D and [Santos and Woodford \(1997, Proposition 2.2\)](#)).

**Lemma 6.2** (Trade in the limit). *Under the gains from trade hypothesis, as  $\epsilon$  in  $(0, 1)$  vanishes, no sequence of competitive equilibrium allocations in the perturbed economy  $\mathcal{E}^\epsilon$  can converge to autarky uniformly.*

Unfortunately, this established property is not powerful enough to deliver by itself the existence of an equilibrium with trade in the limit. Indeed, it requires uniform convergence and, in general, sequences of perturbed equilibria may not converge uniformly to a limit equilibrium. However, we exploit the lack of uniform convergence to autarky to extract a sequence of perturbed equilibria (pointwise) converging to a limit equilibrium with trade. We preliminarily verify that the limit remains away from autarky and bounded. For given  $\epsilon$  in  $(0, 1)$ , we denote by  $(c^\epsilon, v^\epsilon, g^\epsilon)$  in  $C \times V \times G$  a competitive equilibrium of the perturbed economy  $\mathcal{E}^\epsilon$ .

**Lemma 6.3** (Bounds). *Under the gains from trade hypothesis, given any sequence of competitive equilibria in the perturbed economy  $\mathcal{E}^\epsilon$ ,*

$$\liminf_{\epsilon \rightarrow 0} \sup_{t \in \mathbb{T}} \|v_t^\epsilon\|_\infty > 0, \quad (6.1)$$

and

$$\limsup_{\epsilon \rightarrow 0} \sup_{t \in \mathbb{T}} \|g_t^\epsilon\|_\infty < \infty. \quad (6.2)$$

The most delicate implication of Lemma 6.2 is that borrowing does not vanish in the limit; this is condition (6.1). Assuming not, indeed, market clearing would require a progressive contraction of equilibrium debts and credits and, thus, a uniform contraction of trades, contradicting Lemma 6.2. To establish that debt limits do not explode, this is condition (6.2), we observe that an individual would otherwise be able to afford arbitrarily large consumption for long time, by issuing large amounts of debt, and then secure a reservation utility after default, a situation which is inconsistent with the fact that resources are limited in the economy and this large utility value is not feasible.

We now argue that debt is sustainable at equilibrium. In particular, we show that an equilibrium with trade in the original economy can be approached as the (pointwise) limit of a sequence of equilibria in the perturbed economy. A peculiar complication arises because of the endogenous determination of debt limits that is absent in Bewley (1980, 1983).<sup>18</sup>

**Proposition 6.1** (Existence). *Under the gains from trade hypothesis, a non-autarkic equilibrium with self-enforcing debt exists.*

---

<sup>18</sup>Under complete markets it is unnecessary to explicitly consider the not-too-tight condition (3.3) for debt limits because of the equivalence established by Hellwig and Lorenzoni (2009, Theorem 1). In sequential economies with permanent exclusion from markets upon default (e.g., Alvarez and Jermann (2000)), the existence of competitive equilibrium is proved via Welfare Theorems and the method is not available in our economy. Neither can we use the proof in Kehoe and Levine (1993, Proposition 6), because default is there precluded by a direct restriction of consumption plans.

The competitive equilibrium with self-enforcing debt will in general be distinct from a [Bewley \(1980, 1983\)](#) monetary equilibrium of the same economy.<sup>19</sup> Furthermore, when  $\gamma(q) < 1$ , as it happens in our examples, no speculative bubble occurs at equilibrium with self-enforcing debt and debt is valued because of implied future repayments. We add a short comment on welfare comparison.

An adaptation of our approach is suitable as an alternative method to establish existence of a monetary equilibrium in the economy in [Bewley \(1980, 1983\)](#). To this purpose, the gains from trade hypothesis can be more permissive; that is,  $\rho(q^0) > 1$  as opposed to  $\gamma(q^0) > 1$ . One way of interpreting this difference is that a risk-free bond implements only uncontingent transfers, whereas the transfer of resources, at a monetary equilibrium, may be contingent because the real value of money may vary across states of nature. This may suggest that money is a socially superior contrivance to execute intertemporal trade. However, a welfare comparison is ambiguous due to conflicting effects: money can only circulate as a bubble and this enforces zero rate of interest; private debt, on the other side, is compatible with recurrently positive rate of interest; because of impatience, a positive rate of interest may be less distortionary and may permit more efficient intertemporal trades, even if uncontingent.

## 7 Markov pricing

We complement our analysis with the examination of incentives to default in a *partial* equilibrium framework. The pricing kernel is fixed exogenously and follows a simple Markov process.<sup>20</sup> We provide conditions under which default is unprofitable and, at the same time, the natural debt limit (the least present value of future endowment) is finite. In other terms, self-enforcing debt limits exist and do not allow for roll-over. This reveals a failure of [Bulow and Rogoff \(1989a\)](#) when some risks are uninsurable. In addition, the simplified framework allows for a better understanding of the implicit enforcement mechanism.

Our analysis may be of independent interest for the sovereign debt literature, originated by [Eaton and Gersovitz \(1981\)](#). In the traditional framework, the pricing kernel is given by the valuation of risk-neutral creditors. It has however been noticed, in [Arellano \(2008, Section D\)](#), that risk-neutral pricing entails risk premia that are inconsistent with empirical observations. Our approach encompasses risk-averse creditors. This induces time variation in the rate of interest and risk premium through the sensitivity of the lender's stochastic discount factor (the lender's marginal rate of substitution) along the business cycle or with respect to uninsured idiosyncratic risks.

Recently, [Auclert and Rognlie \(2016\)](#) and [Bloise, Polemarchakis, and Vailakis \(2017\)](#) showed that [Bulow and Rogoff \(1989a\)](#) extends to incomplete markets.

---

<sup>19</sup>When money (an infinite-maturity asset with no intrinsic value) is traded, under conditions which ensure its existence, our economy admits a (Bewley-type) competitive equilibrium in which money serves as the only store of value, debt cannot be credibly issued (that is,  $g^i = 0$ ) and the market for the risk-free bond remains inactive.

<sup>20</sup>We remark again that this will not in general happen at a competitive equilibrium.

In [Auclert and Rognlie \(2016\)](#), a risk-free bond is the only asset and the pricing kernel is given by a risk-neutral lender with constant discount factor. Under these conditions, because the price of the risk-free bond is constant, the dominant roots coincide and are less than unity; that is,

$$\gamma(q) = \rho(q) < 1.$$

[Bloise, Polemarchakis, and Vailakis \(2017\)](#) study a more general framework with several securities and a time-varying pricing kernel. Under these conditions, the dominant roots are in general distinct; that is,  $\gamma(q) < \rho(q)$ . They show that, when  $\rho(q) < 1$ , debt is unsustainable, as the sovereign would profit from defaulting at some contingency, saving on repayments and paying upfront for the same insurance contract. This situation occurs when

$$\gamma(q) \leq \rho(q) < 1.$$

We extend the analysis on default incentives further by examining the case where

$$\gamma(q) < 1 < \rho(q).$$

As  $\rho(q) > 1$ , the rate of interest can be negative for long phases, self-insurance becomes too costly and debt repayment is more convenient. As  $\gamma(q) < 1$ , the natural debt limit is finite and debt is not rolled-over.<sup>21</sup>

We assume that uncertainty is described by a Markov process with strictly positive transitions  $\Pi : S \rightarrow \Delta(S)$  on a finite state space  $S$ . A finite set of securities  $J$  is traded at price  $q_s$  in  $\mathbb{R}^J$  in state  $s$  in  $S$ , each delivering a payoff  $R_{s,\hat{s}}^j$  in  $\mathbb{R}$  in state  $\hat{s}$  in  $S$  in the following period. Debt limits are given as  $g$  in  $\mathbb{R}_+^S$ . They are self-enforcing whenever, in every state  $s$  in  $S$ ,

$$J_s(-g_s, g) = J_s(0, 0),$$

where  $J_s(v_s, g)$  is the indirect utility in state  $s$  in  $S$  beginning with initial wealth  $v_s$  in  $\mathbb{R}$  and subject to debt limits  $g$  in  $\mathbb{R}_+^S$  over the entire infinite horizon.

Why is debt sustainable? A comparison with complete markets helps the understanding. As argued by [Hellwig and Lorenzoni \(2009, Theorem 1\)](#), with a complete set of contingent claims, debt is sustainable only if it can be rolled-over exactly and, as we show in [Proposition 5.1](#), this occurs only if the dominant root is equal to unity; that is, long-term rate of interest is zero. A corresponding condition when markets are incomplete would be  $\gamma(q) = 1$  and, in such a situation, debt can be rolled-over without exploding over time, because the long-term rate of interest is not positive. However, exact roll over would in general require contingent transfers and these are not feasible due to market incompleteness. Debt roll-over is necessarily *inexact* and permits additional consumption occasionally. Hence, this situation is more favourable than no

---

<sup>21</sup>In addition,  $\gamma(q) < 1$  is a necessary condition when the pricing kernel is derived from the lender's expected utility with discounting, because the valuation of infinite income streams would not be finite otherwise.

borrowing and debt limits admitting debt roll-over are too loose. For a slight contraction of  $\gamma(q) < 1$ , those debt limits remain loose, whereas natural debt limits are finite and are too tight. As a result, limits for self-enforcing debt will exist in between limits allowing for debt roll-over, which are too loose, and the natural debt limits, which are too tight.

**Proposition 7.1** (Sustainable debt). *Non-trivial self-enforcing debt limits exist if*

$$\gamma(q) < 1 < \rho(q),$$

*provided that (arbitrage-free) prices are in a sufficiently small neighbourhood around  $q^*$  in  $Q$  such that  $\gamma(q^*) = 1$  and  $\rho(q^*) > 1$ .*

We add a short comment on admitting default, as in [Eaton and Gersovitz \(1981\)](#) and, more recently, in [Arellano \(2008\)](#). For our purposes, default enhances debt sustainability, because it increases the value of market participation for the borrower. Thus, under conditions in which debt is sustainable when default is not allowed, so will be when default can occur and the price of the bond reflects the risk of default. In the latter case, obviously, debt is sustainable in the sense that lenders are willing to supply credit, though anticipating default in some future contingencies.

## 8 Conclusion

We have shown that, under incomplete markets, private debt is sustainable by the mere reputation for repayment. The implicit enforcement mechanism relies on a high cost of self-insurance compared with the privilege of issuing debt when the rate of interest is low. Private debt reflects the value of expected future repayments and, differently from [Hellwig and Lorenzoni \(2009\)](#), does not circulate as a speculative bubble. We interpret this as a genuine failure of the claim in [Bulow and Rogoff \(1989a\)](#) that lending must be supported by direct sanctions available to creditors.

We have also established the existence of a competitive equilibrium when default carries only a ban from ever borrowing in financial markets. Private debt is issued and traded as the only store of value so as to support risk-sharing. In general, debt cannot be rolled over and is allocationally distinct from outside money. Beyond ensuring existence, our strategy of proof reveals conditions for mutually beneficial trades in a default-free bond.

A distinctive feature of self-enforcing debt under complete markets, in [Hellwig and Lorenzoni \(2009\)](#), is that debt can be exactly rolled over. In other terms, debt is issued by private individuals and is valued as a speculative bubble or, according to [Bulow and Rogoff \(1989a\)](#), as a Ponzi-type reputational contract. From an individual perspective, even if debt is rolled over, single creditors receive repayments, as when investors sell a speculative bubble held in their portfolio and collect the expected return as for any other security. Socially, however, private debt is not backed by any future repayments, while, in general,

it reflects its fundamental value under incomplete markets. This has important repercussions for the determinacy of equilibrium.

Under complete markets, at a competitive equilibrium, the amount of debt that can be rolled over by each single individual is unrelated to fundamentals. Indeed, in [Hellwig and Lorenzoni \(2009\)](#), Theorem 1) any process of debt limits that allow for exact roll-over is self-enforcing. As a result, debt privileges only derive from an unspecified process of expectations formation and, hence, competitive equilibrium is *indeterminate*: depending on expectations, an individual is allowed to borrow more or less and this affects the effective distribution of wealth; that is, initial financial assets, or liabilities, plus future borrowing capacity.<sup>22</sup> When markets are incomplete, instead, self-enforcing debt truly reflects incentives for repayment and, so, it is intimately related to market conditions and, hence, to fundamentals. The obvious source of indeterminacy disappears when debt cannot be rolled over.

<sup>22</sup>As clarified by the example in [Hellwig and Lorenzoni \(2009\)](#), Supplementary material), when a complete set of contingent claims is traded, there is a continuum of competitive equilibria with self-enforcing debt. In particular, given an initial (balanced) distribution of claims and debts in the economy with self-enforcing debt, the multiplicity corresponds to an open set of initial distributions of shares into the unbacked public debt in the equivalent institutional framework.

## A Proofs

*Proof of Lemma 3.1.* By individual rationality, and using Assumptions 3.1-3.2, at every  $t$  in  $\mathbb{T}$ ,

$$\begin{aligned}
u^i(c_t^i) + \left( \frac{\delta}{1-\delta} \right) \sup_{\hat{c}^i \in \mathbb{R}_+} u^i(\hat{c}^i) &\geq U_t^i(c^i) \\
&\geq U_t^i(e^i) \\
&\geq U_t^i(\epsilon_t e) \\
&\geq \left( \frac{1}{1-\delta} \right) u^i(\epsilon_t \eta),
\end{aligned}$$

where  $\eta > 0$  is the uniform lower bound for the aggregate endowment; that is,  $e_t \geq \eta$  at every  $t$  in  $\mathbb{T}$ . By the Strong Inada Condition (Assumption 3.2), this suffices to prove the claim.  $\square$

*Proof of Proposition 5.1.* Consider any individual  $i$  in  $I$  with persistent debt roll-over and drop the index  $i$  in  $I$  in order to simplify notation. The roll-over property immediately implies  $\gamma(q) \geq 1$  and, hence, we show that  $\gamma(q) \leq 1$ . Supposing not, there exists  $\gamma > 1$  such that, for some non-zero process  $\hat{b}$  in  $L^+(e)$ , at every  $t$  in  $\mathbb{T}$ ,

$$\gamma \hat{b}_t \leq -\Pi_t(-\hat{b}_{t+1}).$$

As a consequence, we can find a portfolio process  $\Delta z$  in  $Z$  such that, at every  $t$  in  $\mathbb{T}$ ,

$$q_t(\Delta z_t) \leq -\gamma \hat{b}_t \leq -\hat{b}_t \quad (\text{A.1})$$

and

$$-\hat{b}_{t+1} \leq R_{t,t+1}(\Delta z_t). \quad (\text{A.2})$$

We now show that this portfolio process allows for super-replicating the optimal plan under no borrowing, thus delivering a contradiction.

Define  $\lambda$  in  $\mathbb{R}_+$  as the greatest value satisfying  $g \geq \lambda \hat{b}$ . Because debt limits are in the interior of  $L^+(e)$ ,  $\lambda > 0$  and, at no loss of generality,  $\lambda = 1$ . Thus,  $g \geq \hat{b}$  and, at some contingency,  $g_t < \gamma \hat{b}_t$ , since otherwise  $g \geq \gamma \hat{b}$ , a contradiction as  $\gamma > 1$ . At no loss of generality, to simplify notation, assume that  $g_0 < \gamma \hat{b}_0$  and, so,  $\hat{b}_0 > 0$ . We argue that

$$V_0(-g_0, g) > V_0(-\gamma \hat{b}_0, \hat{b}) \geq V_0(0, 0),$$

a contradiction. The first strict inequality is obvious, because  $g \geq \hat{b}$  and  $-g_0 > -\gamma \hat{b}_0$ . For the other inequality, take the plan which is optimal at  $(0, 0)$  in  $L_0 \times L^+$  and replicate it at  $(-\gamma \hat{b}_0, \hat{b})$  in  $L_0 \times L^+$  by translation; that is,

$$z_t \mapsto z_t + \Delta z_t.$$

By conditions (A.1)-(A.2), this is feasible, revealing a contradiction.

Clearly,  $\rho(q) \geq \gamma(q) = 1$ . It only remains to verify that  $\rho(q) \leq 1$ . The roll-over component  $b$  in the interior of  $L^+(e)$  satisfies conditions (A.1)-(A.2) with  $\gamma = 1$ . If an inequality is strict at some contingency, then the previous replication argument would imply

$$V_0(-g_0, g) > V_0(0, 0),$$

a contradiction. This means that, at every  $t$  in  $\mathbb{T}$ ,

$$b_t = \Pi_t(b_{t+1}) = -\Pi_t(-b_{t+1}). \quad (\text{A.3})$$

Suppose that, given  $\rho$  in  $\mathbb{R}_+$ , there is a process  $\hat{b}$  in  $L^+(e)$  such that

$$\rho \hat{b}_t \leq \Pi_t(\hat{b}_{t+1}).$$

Let  $\lambda$  in  $\mathbb{R}_+$  be the maximum value such that  $\lambda \hat{b} \leq b$  and, at no loss of generality, assume that  $\lambda = 1$ . Monotonicity yields, at every  $t$  in  $\mathbb{T}$ ,

$$\rho \hat{b}_t \leq \Pi_t(\hat{b}_{t+1}) \leq \Pi_t(b_{t+1}) \leq b_t,$$

so that  $\rho \leq 1$ . This proves our claim.  $\square$

**Claim A.1.** Under condition (5.3),

$$q_s \geq \max_{i \in I} \delta \left( \frac{c_s^i}{\sum_{\hat{s} \in S} \mu_{\hat{s}} c_{\hat{s}}^i} \right)^\sigma > 1.$$

*Proof of Claim A.1.* To obtain a contradiction, assume that, for every individual  $i$  in  $I$ ,

$$\delta \left( \frac{c_s^i}{\sum_{\hat{s} \in S} \mu_{\hat{s}} c_{\hat{s}}^i} \right)^\sigma \leq 1.$$

This implies

$$\delta^{\frac{1}{\sigma}} \sum_{i \in I} c_s^i \leq \sum_{i \in I} \sum_{\hat{s} \in S} \mu_{\hat{s}} c_{\hat{s}}^i \leq \sum_{\hat{s} \in S} \mu_{\hat{s}} \sum_{i \in I} c_{\hat{s}}^i,$$

thus violating condition (5.3).  $\square$

*Proof of Lemma 6.1.* Let  $f^{i,\epsilon}$  in  $L^+$  be the maximum debt that can be re-payed, beginning from each contingency, out of the share  $\epsilon$  in  $(0, 1)$  of the endowment. This is well-defined and satisfies, at every  $t$  in  $\mathbb{T}$ ,

$$0 \leq f_t^{i,\epsilon} \leq \epsilon e_t^i - \Pi_t^\epsilon(-g_{t+1}^{i,\epsilon}).$$

The upper bound corresponds to devoting the current share of the endowment to debt repayment and borrowing up to the limit. At every  $t$  in  $\mathbb{T}$ , an individual can always repay back a debt not exceeding  $f_t^{i,\epsilon}$  in  $L_t^+$  out of share  $\epsilon$  in  $(0, 1)$  of the endowment and, at the same time, implement the optimal plan under no borrowing with no initial wealth, so that

$$J_t^{i,\epsilon}(-f_t^{i,\epsilon}, g^{i,\epsilon}) \geq J_t^{i,\epsilon}(0, 0).$$

We claim that  $g_t^{i,\epsilon} \geq f_t^{i,\epsilon}$ . Indeed, supposing not, at some contingency,

$$J_t^{i,\epsilon}(-g_t^{i,\epsilon}, g^{i,\epsilon}) > J_t^{i,\epsilon}(-f_t^{i,\epsilon}, g^{i,\epsilon}) \geq J_t^{i,\epsilon}(0, 0),$$

a contradiction. Hence, adapted process  $f^{i,\epsilon}$  in  $L^+$  satisfies, at every  $t$  in  $\mathbb{T}$ , the recursive condition

$$f_t^{i,\epsilon} = \epsilon e_t^i - \Pi_t^\epsilon(-f_{t+1}^{i,\epsilon}).$$

This suffices to prove the claim, as  $e^i$  lies in the interior of  $L^+(e)$ .  $\square$

*Proof of Lemma 6.2.* We assume uniform convergence to autarky and argue by contradiction. At no loss of generality, the price of the bond satisfies, at every  $t$  in  $\mathbb{T}$ ,

$$q_t^\epsilon = \max_{i \in I} \delta \mathbb{E}_t \frac{\nabla u^i(c_{t+1}^{i,\epsilon})}{\nabla u^i(c_t^{i,\epsilon})}.$$

By the hypothesis on gains from trade, there exists  $\gamma > 1$  such that, for some non-zero  $b^0$  in  $L^+(e)$ , at every  $t$  in  $\mathbb{T}$ ,

$$\gamma b_t^0 \leq -\Pi_t^0(-b_{t+1}^0).$$

As convergence is uniform, for every sufficiently small  $\epsilon$  in  $(0, 1)$ ,

$$b_t^0 \leq -\frac{1}{\gamma} \Pi_t^0(-b_{t+1}^0) \leq -\Pi_t^\epsilon(-b_{t+1}^0),$$

where we use the fact that  $q_t^0 \leq \gamma q_t^\epsilon$  in computing the minimum-expenditure portfolio. Let  $\lambda > 0$  be the greatest value such that  $\lambda b^0 \leq f^\epsilon$  and, at no loss of generality, assume that  $\lambda = 1$ , where  $f^\epsilon$  in the interior of  $L^+(e)$  is given in Lemma 6.1. Monotonicity implies

$$b_t^0 \ll e_t - \Pi_t^\epsilon(-b_{t+1}^0) \leq e_t - \Pi_t^\epsilon(-f_{t+1}^\epsilon) \leq f_t^\epsilon,$$

a contradiction.  $\square$

*Proof of Lemma 6.3.* To establish condition (6.1), we argue by contradiction. Supposing not,  $\liminf_{\epsilon \rightarrow 0} \eta_\epsilon = 0$ , where  $\eta_\epsilon = \sup_{t \in \mathbb{T}} \|v_t^\epsilon\|_\infty$ . For every individual  $i$  in  $I$ , the budget constraint imposes, at every  $t$  in  $\mathbb{T}$ ,

$$v_t^i = (c_t^i - e_t^i) + q_t v_{t+1}^i.$$

Furthermore, by first-order conditions,

$$\delta \mathbb{E}_t \frac{\nabla u^i(c_{t+1}^i)}{\nabla u^i(c_t^i)} \leq q_t,$$

with the equality when the individual is saving. Thus,

$$v_t^i \leq (c_t^i - e_t^i) + \delta \mathbb{E}_t \frac{\nabla u^i(c_{t+1}^i)}{\nabla u^i(c_t^i)} v_{t+1}^i.$$

Evaluating at a competitive equilibrium of the perturbed economy  $\mathcal{E}^\epsilon$ , and using the bound on wealth,

$$-\eta_\epsilon \leq (c_t^{i,\epsilon} - e_t^i) + \delta \mathbb{E}_t \frac{\nabla u^i(c_{t+1}^{i,\epsilon})}{\nabla u^i(c_t^{i,\epsilon})} \eta_\epsilon.$$

As the economy is bounded, by Lemma 3.1, marginal rates of substitution are uniformly bounded, so that, for some sufficiently large  $\kappa > 0$ ,

$$\left( c_t^{i,\epsilon} - e_t^i \right)^- \leq \eta_\epsilon + \kappa \eta_\epsilon.$$

By feasibility, possibly extracting a subsequence, this implies uniform convergence to autarky, which is ruled out by Lemma 6.2. This shows that condition (6.1) holds true.

We now prove that debt limits remain bounded in the perturbed economy  $\mathcal{E}^\epsilon$ , so that condition (6.2) holds true. At no loss of generality, we can assume that, at every  $t$  in  $\mathbb{T}$ ,

$$q_t^\epsilon = \max_{i \in I} \delta \mathbb{E}_t \frac{\nabla u^i(c_{t+1}^{i,\epsilon})}{\nabla u^i(c_t^{i,\epsilon})}.$$

Indeed, if not, the price process can be replaced without affecting optimal consumption and bond holding. Marginal rates of substitution are uniformly bounded because consumption is uniformly bounded from below (by Lemma 3.1) and from above (by material feasibility). Hence, there exist adapted processes  $q$  and  $\bar{q}$  in the interior of  $L^+(e)$  such that  $q \leq q^\epsilon \leq \bar{q}$ .

Preliminarily notice that equilibrium wealth is uniformly bounded, that is,

$$\limsup_{\epsilon \rightarrow 0} \sup_{t \in \mathbb{T}} \|v_t^\epsilon\|_\infty < \infty.$$

In fact, as prices remain bounded, out of a large enough financial wealth, individual  $i$  in  $I$  can afford a consumption plan  $e^i + \bar{e}^t$ , where  $\bar{e}^t$  in  $L^+$  is the aggregate endowment truncated at period  $t$  in  $\mathbb{T}$ . By impatience, for every individual  $i$  in  $I$ ,

$$\lim_{t \rightarrow \infty} U_0^i(e^i + \bar{e}^t) > U_0^i(\bar{e}) \geq U_0^i(c^{i,\epsilon}).$$

Thus, if equilibrium wealth is unbounded, some individual would be able to afford an unfeasibly large value in utility, a contradiction.

Suppose that, by an appropriate choice of the initial state  $s$  in  $S$ , there is a sequence of equilibria in the perturbed economy  $\mathcal{E}^\epsilon$  such that, for some individual  $i$  in  $I$ ,  $\lim_{\epsilon \rightarrow 0} g_0^{i,\epsilon} = \infty$ . Notice that debt limits satisfy, at every  $t$  in  $\mathbb{T}$ ,

$$g_t^{i,\epsilon} \leq e_t^i - \Pi_t^\epsilon(-g_{t+1}^{i,\epsilon}) \leq e_t^i - \bar{\Pi}_t(-g_{t+1}^{i,\epsilon}),$$

because otherwise the budget set would be empty. The bound in the extreme right hand-side is computed using the pricing functional  $\bar{\Pi}_t : L_{t+1} \rightarrow L_t$  corresponding to the upper bound on the price process for the risk-free bond. It follows that debt limits diverge at every  $t$  in  $\mathbb{T}$ . Possibly extracting a subsequence, it can be assumed that the sequence of consumption plans  $(c^{i,\epsilon})_{\epsilon > 0}$  in  $C^i$  converges to a consumption plan  $c^i$  in  $C^i$ . Let  $\hat{c}^i$  in  $C^i$  be  $c_t^i + e_t$  up to period  $\hat{t}$  in  $\mathbb{T}$  and  $(1 - \hat{\epsilon})e_t^i$  at any other following period  $t$  in  $\mathbb{T}$ , where  $\hat{\epsilon}$  lies

in  $(0, 1)$ . By impatience, period  $\hat{t}$  in  $\mathbb{T}$  can be chosen sufficiently large so that  $U_0^i(\hat{c}^i) > U_0^i(c^{i,\epsilon})$  for every sufficiently small  $\epsilon$  in  $(0, \hat{\epsilon})$ . Let  $\hat{v}^{i,\epsilon}$  in  $L$  be a financial plan supporting  $\hat{c}^i$  in  $C^i$ , from bounded initial wealth  $v_0^{i,\epsilon}$  in  $L_0$ , ignoring solvency constraints; that is, such that, at every  $t$  in  $\mathbb{T}$ ,

$$q_t^\epsilon \hat{v}_{t+1}^{i,\epsilon} + \hat{c}_t^i = e_t^i + \hat{v}_t^{i,\epsilon}.$$

When the individual defaults in period  $\hat{t} + 1$  in  $\mathbb{T}$ , she can secure a level of utility at least equal to  $U_{\hat{t}+1}^i((1 - \hat{\epsilon})e^i)$ . Thus, we only need to verify that  $\hat{v}_{t+1}^{i,\epsilon} \geq -g_{t+1}^{i,\epsilon}$  up to period  $\hat{t}$  in  $\mathbb{T}$ . This is certainly satisfied as debt limits diverge and the financial plan remains bounded on the finite horizon, thus yielding a contradiction.  $\square$

*Proof of Proposition 6.1.* Given a perturbation  $\epsilon$  in  $(0, 1)$ , we denote  $(c^\epsilon, v^\epsilon, g^\epsilon)$  in  $C \times V \times G$  a competitive equilibrium of the perturbed economy  $\mathcal{E}^\epsilon$ . At no loss of generality, the price of the bond is determined, at every  $t$  in  $\mathbb{T}$ , by

$$q_t^\epsilon = \max_{i \in I} \delta \mathbb{E}_t \frac{\nabla u^i(c_{t+1}^{i,\epsilon})}{\nabla u^i(c_t^{i,\epsilon})}.$$

By choosing the initial state  $s$  in  $S$  appropriately, we can extract a sequence of equilibrium plans  $(c^\epsilon, v^\epsilon, g^\epsilon)_{\epsilon > 0}$  in  $C \times V \times G$  (pointwise) converging to plans  $(c, v, g)$  in  $C \times V \times G$  such that  $\|v_0\|_\infty > 0$ . We need to verify that plans are optimal and debt limits are self-enforcing. We then establish that the limit equilibrium necessarily implies trade beginning from any initial state  $s$  in  $S$ .

We first show that, at every  $t$  in  $\mathbb{T}$ ,  $\lim_{\epsilon \rightarrow 0} J_t^{i,\epsilon}(0, 0) = J_t^i(0, 0)$  and, just to simplify notation, we assume that  $t = 0$ . To this purpose, consider the (otherwise identical) program truncated at  $\hat{t}$  in  $\mathbb{T}$ . Notice that, as this is basically a maximization program over a finite horizon, by canonical arguments,

$$\lim_{\epsilon \rightarrow 0} \left| J_0^{i,\hat{t}}(0, 0) - J_0^{i,\epsilon,\hat{t}}(0, 0) \right| = 0.$$

Any budget feasible plan in the untruncated program can be replicated in the truncated program over the truncated finite horizon. Thus, as continuation utility is bounded from above by some sufficiently large  $\Delta^* > 0$  (because utility is bounded from above) and from below by some sufficiently small  $\Delta_* < 0$  (because a fraction of the endowment can be consumed), we obtain, for every sufficiently small  $\epsilon$  in  $(0, 1)$ ,

$$\left| J_0^{i,\epsilon}(0, 0) - J_0^{i,\epsilon,\hat{t}}(0, 0) \right| \leq \delta^{\hat{t}+1} (\Delta^* - \Delta_*).$$

and

$$\left| J_0^i(0, 0) - J_0^{i,\hat{t}}(0, 0) \right| \leq \delta^{\hat{t}+1} (\Delta^* - \Delta_*).$$

By a conventional triangular decomposition, this suffices to prove our claim. Similarly, we establish that, at every  $t$  in  $\mathbb{T}$ ,  $\lim_{\epsilon \rightarrow 0} J_t^{i,\epsilon}(-g_t^{i,\epsilon}, g^{i,\epsilon}) = J_t^i(-g_t^i, g^i)$ .

Clearly, the plan in the limit satisfies budget and solvency constraints. Supposing that it is not optimal, for all sufficiently small  $\epsilon$  in  $(0, 1)$ ,  $J_0^i(v_0^i, g^i) > J_0^{i,\epsilon}(v_0^{i,\epsilon}, g^{i,\epsilon}) + \Delta$  for some  $\Delta > 0$ . As a consequence, for any truncation  $\hat{t}$  in  $\mathbb{T}$ ,

$$\begin{aligned} J_0^{i,\hat{t}}(v_0^i, g^i) + \delta^{\hat{t}+1} \Delta^* &\geq \\ J_0^i(v_0^i, g^i) &> J_0^{i,\epsilon}(v_0^{i,\epsilon}, g^{i,\epsilon}) + \Delta \\ &\geq J_0^{i,\epsilon,\hat{t}}(v_0^{i,\epsilon}, g^{i,\epsilon}) + \delta^{\hat{t}+1} \Delta_* + \Delta, \end{aligned}$$

where the upper bound  $\Delta^* > 0$  and the lower bound  $\Delta_*$  are given as in the previous step. For a sufficiently large  $\hat{t}$  in  $\mathbb{T}$ , this implies that  $J_0^{i,\hat{t}}(v_0^i, g^i) > J_0^{i,\epsilon,\hat{t}}(v_0^{i,\epsilon}, g^{i,\epsilon}) + \Delta$  for every sufficiently small  $\epsilon$  in  $(0, 1)$ , thus delivering a contradiction because the value of the truncated program varies continuously.

We finally verify that there is a limit equilibrium involving trade from any initial state  $s$  in  $S$ . Indeed, supposing that trade always vanishes in the continuation economy whenever a state  $s$  in  $S$  is reached, no wealth is transferred to this state and, so, because transition probabilities are strictly positive and only a risk-free bond is traded, to any state; that is,  $v_{t+1} = 0$  for every  $t$  in  $\mathbb{T}$ . Hence, the initial allocation itself is autarkic, contradicting the fact that the limit is selected so that  $\|v_0\|_\infty > 0$ . As a result, a non-autarkic equilibrium exists beginning from any state  $s$  in  $S$ .  $\square$

*Proof of Proposition 7.1.* We preliminarily consider the limit case when  $\gamma(q^*) = 1$  and  $\rho(q^*) > 1$ . To this purpose, let  $\underline{g}$  in  $\mathbb{R}_+^S$  be the lower dominant eigenvector (see Claim D.4). For every  $s$  in  $S$ , there exists a portfolio  $\Delta z_s$  in  $\mathbb{R}^J$  such that

$$q_s^*(-\Delta z_s) \leq -\underline{g}_s$$

and, at every  $\hat{s}$  in  $S$ ,

$$-\underline{g}_{\hat{s}} \leq R_{s,\hat{s}}(-\Delta z_s).$$

Moreover, since the eigenvector is not in the market span (because  $\gamma(q^*) < \rho(q^*)$ ), the last inequality is strict in at least one state  $\hat{s}$  in  $S$ . We shall show that, for every state  $s$  in  $S$ ,

$$J_s^*(-\underline{g}_s, \underline{g}) > J_s^*(0, 0), \tag{A.4}$$

where the value function is evaluated at prices  $q^*$  in  $Q$ .

Let  $\mathcal{S}_s$  be the space of all partial histories beginning from state  $s$  in  $S$ , and let  $s(\sigma)$  be the state in  $S$  occurring at the end of partial history  $\sigma$  in  $\mathcal{S}_s$ ; that is,  $\sigma = (s_0, s_1, \dots, s_{t-1}, s_t)$  in  $S^{t+1}$  with  $s_0 = s$  and  $s_t = s(\sigma)$ . The optimal plan under no borrowing and no initial wealth satisfies, at every  $\sigma$  in  $\mathcal{S}_s$ ,

$$q_{s(\sigma)}^*(z_\sigma) + (c_\sigma - e_{s(\sigma)}) \leq w_\sigma$$

and, at every continuation history  $\hat{\sigma} = (\sigma, \hat{s})$  in  $\mathcal{S}_s$ ,

$$0 \leq w_{\hat{\sigma}} = R_{s(\sigma), s(\hat{\sigma})}(z_{\sigma}).$$

Adding the above identified portfolio,

$$q_{s(\sigma)}^*(z_{\sigma} - \Delta z_{s(\sigma)}) + (c_{\sigma} - e_{s(\sigma)}) \leq w_{\sigma} - g_{s(\sigma)}$$

and, at every continuation history  $\hat{\sigma}$  in  $\mathcal{S}_s$ ,

$$-g_{s(\hat{\sigma})} \leq w_{\hat{\sigma}} - g_{s(\hat{\sigma})} \leq R_{s(\sigma), s(\hat{\sigma})}(z_{\sigma} - \Delta z_{s(\sigma)}).$$

The last inequality is strict for at least some continuation history  $\hat{\sigma}$  in  $\mathcal{S}_s$ . By strict monotonicity of preferences, this proves the claim.

We now show that condition (A.4) continues to hold true after a perturbation of prices such that  $\gamma(q) < 1 < \rho(q)$ . Provided this perturbation is sufficiently small, by Claim D.6, there exists a minimum consumption  $\underline{c}$  in  $\mathbb{R}_{++}^S$  such that, at every  $s$  in  $S$ ,

$$g_s \leq (e_s - \underline{c}_s) - \Pi_s(-g).$$

The existence of a budget-feasible minimum consumption avoids complications related to unbounded utility. Consider the Bellman operator defined, at every  $s$  in  $S$ , by

$$(TJ)_s(v_s, q) = \sup u(c_s) + \delta \sum_{\hat{s} \in S} \mu_{s, \hat{s}} J_{\hat{s}}(R_{s, \hat{s}}(z_s), q)$$

subject to

$$q_s(z_s) + (c_s - e_s) \leq v_s$$

and, at every  $\hat{s}$  in  $S$ ,

$$-g_s \leq R_{s, \hat{s}}(z_s).$$

This operator  $T : \mathcal{J} \rightarrow \mathcal{J}$  acts on the space of all bounded maps  $J : D \rightarrow \mathbb{R}$ , where  $D$  contains all  $v \geq -g$  in  $\mathbb{R}_{++}^S$  and all arbitrage-free prices in a open neighborhood of  $q^*$  in  $Q$ . The operator is a contraction (by Blackwell discounting) and, hence, admits a unique fixed point. Consider the feasible correspondence  $F : D \rightarrow \mathbb{R}_+ \times \mathbb{R}^J$ . This correspondence is continuous with non-empty compact values. By Berge's Maximum Theorem, when  $J$  in  $\mathcal{J}$  is continuous, so it  $(TJ)$  in  $\mathcal{J}$ . Hence, the unique fixed point is continuous, which proves the validity of condition (A.4) for any slight perturbation of (arbitrage-free) prices such that  $\gamma(q) < 1 < \rho(q)$ .

As long as  $\gamma(q) < 1$ , natural debt limits  $\bar{g}$  in  $\mathbb{R}_{++}^S$  are finite (see Claim D.3) and, at no loss of generality,  $g \leq \bar{g}$ , because they grow unboundedly as  $\gamma(q)$  approaches  $\gamma(q^*) = 1$ . Define the mapping  $f : [g, \bar{g}] \rightarrow [g, \bar{g}]$  by the formula

$$J_s(-f_s(g), g) = J_s(0, 0).$$

The unique solution exists because, by Inada condition,

$$J_s(-\bar{g}_s, g) < J_s(0, 0)$$

and, by the previous characterization,

$$J_s(-\underline{g}_s, g) \geq J_s(-\underline{g}_s, \underline{g}) > J_s(0, 0).$$

Notice that mapping  $f : [\underline{g}, \bar{g}] \rightarrow [\underline{g}, \bar{g}]$  is monotone. We claim that self-enforcing debt limits  $g$  in  $[\underline{g}, \bar{g}]$  are determined, at every  $s$  in  $S$ , by

$$g_s = \lim_{n \rightarrow \infty} f_s^n(g).$$

Preliminarily observe that, by canonical arguments, at every  $s$  in  $S$ ,

$$J_s(-\underline{g}_s, g) \geq J_s(0, 0).$$

Fix any  $t$  in  $\mathbb{T}$  and let  $J^t$  be the value function corresponding to the truncated program at  $t$  in  $\mathbb{T}$ . As this is a finite-dimensional program, by continuity,

$$J_s^t(-\underline{g}_s, g) = \lim_{n \rightarrow \infty} J_s^t(-f_s^{n+1}(g), f^n(g)).$$

Notice that, after the truncation, the no borrowing value can be secured, because, at every  $s$  in  $S$ ,

$$J_s(-f_s^n(g), f^n(g)) \geq J_s(-f_s^{n+1}(g), f^n(g)) = J_s(0, 0).$$

Therefore, as continuation utility is bounded from above and from below, there exists  $\Delta > 0$  such that

$$|J_s^t(-f_s^{n+1}(g), f^n(g)) - J_s(-f_s^{n+1}(g), f^n(g))| \leq \delta^{t+1} \Delta$$

and

$$|J_s^t(-\underline{g}_s, g) - J_s(-\underline{g}_s, g)| \leq \delta^{t+1} \Delta.$$

This suffices to prove that, at every  $s$  in  $S$ ,

$$J_s(-\underline{g}_s, g) = \lim_{n \rightarrow \infty} J_s(-f_s^{n+1}(g), f^n(g)) = J_s(0, 0),$$

thus establishing the claim.  $\square$

## B Example

We provide a simple example of competitive equilibrium with no debt rollover. In particular, to preserve stationarity, we assume constant marginal utilities and set prices so that one individual is indifferent in each period. The example is non-robust because of this feature. The equilibrium would in general not be stationary for a perturbation of relevant parameters.

The economy consists of two individuals with cyclic endowment. When the endowment of an individual is low,  $\underline{e}$ , the endowment of the other individual

is high,  $\bar{e}$ , with  $\bar{e} > e > 0$ .<sup>23</sup> In addition, an independent and identically distributed shock  $s$  in  $S = \{u, d\}$  affects marginal utility. In particular, when income is low, marginal utility is unitary; when income is high, it is either  $\psi_u$  or  $\psi_d$  with equal probability, where

$$1 \geq \psi_u > \psi_d > 0. \quad (\text{B.1})$$

The only asset is a discount risk-free bond. In order to ensure trade, we set prices so that the high-endowment individual is indifferent between saving and dissaving. In particular, letting  $\delta$  in  $(0, 1)$  be the common discount factor, the price of the bond, depending on state  $s$  in  $S$ , is

$$q_s = \frac{\delta}{\psi_s}. \quad (\text{B.2})$$

To guarantee that the low-endowment individual is willing to borrow, we assume that

$$\min_{s \in S} q_s > \frac{\delta}{2} \sum_{s \in S} \psi_s. \quad (\text{B.3})$$

Under the stated conditions, we characterize the value function explicitly.

Borrowing is allowed up to debt limits  $g = (\bar{g}, g)$  in  $\mathbb{R}_+^S \times \mathbb{R}_+^S$ , where  $\bar{g}_s$  and  $g_s$  are the maximum sustainable debt, depending on endowment, in state  $s$  in  $S$ . Such debt limits are consistent; that is,

$$\bar{g}_s \leq \bar{e} + q_s \min_{s \in S} g_s$$

and

$$g_s \leq e + q_s \min_{s \in S} \bar{g}_s.$$

Indeed, if not, the maximum debt would not be sustainable beginning from one of the states in  $S$ . Each individual is subject to a budget constraint

$$q_s v' + c \leq e + v,$$

whereas the holding of the risk-free bond is restricted by the solvency constraint

$$-\min_{s \in S} g'_s \leq v',$$

where  $g'$  in  $\mathbb{R}_+^S$  is the maximum sustainable debt in the following period. By pricing restrictions (B.2)-(B.3), the individual will be borrowing only when income is high in the next period. As a consequence, the only relevant limit is

$$d = \min_{s \in S} \bar{g}_s.$$

---

<sup>23</sup>Because marginal utilities are constant, high and low endowment play no role and are used only for narrative convenience. We assume that the endowment is sufficiently large so as to ensure positive consumption in all states.

**Claim B.1** (Value function under borrowing). The value function is, when income is low,

$$\underline{J}_s(v) = \underline{e} + v + q_s d + \frac{1}{2} \frac{\delta}{1 - \delta^2} \sum_{s \in S} \psi_s(\bar{e} - d) + \frac{1}{2} \frac{\delta^2}{1 - \delta^2} \sum_{s \in S} (\underline{e} + q_s d)$$

and, when income is high,

$$\bar{J}_s(v) = \psi_s(\bar{e} + v) + \frac{1}{2} \frac{\delta}{1 - \delta^2} \sum_{s \in S} (\underline{e} + q_s d) + \frac{1}{2} \frac{\delta^2}{1 - \delta^2} \sum_{s \in S} \psi_s(\bar{e} - d).$$

*Proof.* When income is low, the maximization program is

$$\max \underline{e} + v - q_s v' + \frac{\delta}{2} \sum_{s \in S} \bar{J}_s(v')$$

subject to

$$\frac{\underline{e} + v}{q_s} \geq v' \geq -\min_{s \in S} \bar{g}_s.$$

This is equivalent to

$$\max \left( -q_s + \frac{\delta}{2} \sum_{s \in S} \psi_s \right) v'.$$

Because of condition (B.3), the only solution is  $v' = -\min_{s \in S} \bar{g}_s$ . Hence,

$$\begin{aligned} \underline{J}_s(v) &= \underline{e} + v + q_s d + \frac{\delta}{2} \sum_{s \in S} \bar{J}_s(-d) \\ &= \underline{e} + v + q_s d + \frac{1}{2} \frac{\delta}{1 - \delta^2} \sum_{s \in S} \psi_s(\bar{e} - d) + \frac{1}{2} \frac{\delta^2}{1 - \delta^2} \sum_{s \in S} (\underline{e} + q_s d), \end{aligned}$$

which is exactly the formula in the claim.

To verify the equation for high income, consider the maximization program

$$\max \psi_s(\bar{e} + v - q_s v') + \frac{\delta}{2} \sum_{s \in S} J_s(v')$$

subject to

$$\frac{\bar{e} + v}{q_s} \geq v' \geq -\min_{s \in S} g_s.$$

This is equivalent to

$$\max (-\psi_s q_s + \delta) v',$$

which is consistent with  $v' = (\bar{e} + v) / q_s$  because of the pricing rule (B.2). Hence,

$$\begin{aligned} \bar{J}_s(v) &= \frac{\delta}{2} \sum_{s \in S} J_s \left( \frac{\bar{e} + v}{q_s} \right) \\ &= \delta \left( \frac{\bar{e} + v}{q_s} \right) + \frac{1}{2} \frac{\delta}{1 - \delta^2} \sum_{s \in S} (\underline{e} + q_s d) + \frac{1}{2} \frac{\delta^2}{1 - \delta^2} \sum_{s \in S} \psi_s(\bar{e} - d) \\ &= \psi_s(\bar{e} + v) + \frac{1}{2} \frac{\delta}{1 - \delta^2} \sum_{s \in S} (\underline{e} + q_s d) + \frac{1}{2} \frac{\delta^2}{1 - \delta^2} \sum_{s \in S} \psi_s(\bar{e} - d), \end{aligned}$$

so proving the claim.  $\square$

To determine debt limits, we now impose the not-too-tight condition; that is,

$$J_s(-g_s) = J_s^0(0),$$

where  $J^0$  is the value function under no borrowing (that is, when  $g = 0$ ). Notice that

$$[\bar{J}_d(-d) - \bar{J}_d^0(0)] - [\bar{J}_u(-d) - \bar{J}_u^0(0)] = (\psi_u - \psi_d)d.$$

Therefore, because of (B.1), the debt limit will be binding in state  $u$  in  $S$ ; that is,  $d = \bar{g}_u < \bar{g}_d$ . The not-too-tight condition is thus

$$\bar{J}_u(-d) = \bar{J}_u^0(0). \quad (\text{B.4})$$

We now show that this condition admits a non-trivial solution for some specification of parameters.

**Claim B.2** (Debt limit). When  $\psi_u = 1$ , there exists  $\psi_d$  in  $(0, \delta)$  such that the not-too-tight condition (B.4) is solved by any sufficiently small  $d > 0$ .

*Proof.* By identification, condition (B.4) is satisfied if and only if

$$\psi_u d = \delta \left( \frac{1}{2} \frac{1}{1-\delta^2} \sum_{s \in S} q_s - \frac{1}{2} \frac{\delta}{1-\delta^2} \sum_{s \in S} \psi_s \right) d.$$

Assuming that  $\psi_u = 1$  (and so that  $q_u = \delta$  by condition (B.2)), the above equation becomes

$$f(\psi_d) = \delta \left( \frac{1}{1-\delta^2} \frac{q_d + \delta}{2} - \frac{\delta}{1-\delta^2} \frac{1 + \psi_d}{2} \right) = 1.$$

When  $\psi_d = \delta$ , then  $q_d = 1$  and

$$f(\delta) = \delta \left( \frac{1}{1-\delta^2} \frac{1 + \delta}{2} - \frac{\delta}{1-\delta^2} \frac{1 + \delta}{2} \right) = \delta \frac{1 - \delta}{1 - \delta^2} \frac{1 + \delta}{2} = \frac{\delta}{2}.$$

When  $\psi_d \rightarrow 0$ , then  $q_d \rightarrow \infty$  and

$$\lim_{\psi_d \rightarrow 0} f(\psi_d) = \infty.$$

Hence, by the Intermediate Value Theorem, a solution exists in  $(0, \delta)$ .  $\square$

In the competitive equilibrium, the individual borrows up to  $d > 0$  when income is low and saves up to  $d > 0$  when income is high. This plan is optimal because the high income individual is exactly indifferent, whereas the low-income individual is constrained. Furthermore, it satisfies market clearing. A distinguished feature of this competitive equilibrium is that debt is sustainable. However, differently from Hellwig and Lorenzoni (2009), debt cannot be rolled over. Indeed, notice that rate of interest is strictly positive in state  $u$  in  $S$  (*i.e.*,  $q_u = \delta$ ). Hence, when debt is refinanced along a sequence of persistent shocks  $u$  in  $S$ , its value grows unboundedly and default is eventually profitable. To enforce repayment, debt limits have to preclude roll-over.

## C Perturbed equilibrium

### C.1 Preliminaries

We here prove the existence of an equilibrium in the perturbed economy  $\mathcal{E}^\epsilon$  for a given  $\epsilon$  in  $(0, 1)$ . As some parts of the proof are rather involved, we only sketch conventional steps and expand those that require more innovative arguments. In order to simplify notation, we drop any explicit reference to the given  $\epsilon$  in  $(0, 1)$ . To establish existence, we artificially force no borrowing out of a finite horizon and progressively relax this additional constraint by taking the limit.

Using Lemma 3.1, by material feasibility and individually rationality, consumption plans are bounded from above by  $\bar{\epsilon} > 0$  and from below by  $\underline{\epsilon} > 0$ . We fix a lower bound  $q$  and a upper bound  $\bar{q}$  in  $L^+$  on prices such that

$$0 < \underline{q}_t < \min_{i \in I} \delta \frac{\nabla u^i(\underline{\epsilon})}{\nabla u^i(\epsilon)} \leq \max_{i \in I} \delta \frac{\nabla u^i(\underline{\epsilon})}{\nabla u^i(\bar{\epsilon})} < \bar{q}_t. \quad (\text{C.1})$$

Both upper bound and lower bound are taken as constant processes. The auctioneer will vary prices in the truncated interval  $Q = [q, \bar{q}] \subset L^+$ .

We assume that, for every individual  $i$  in  $I$ ,  $v_0^i = 0$ . We truncate the economy at some  $s$  in  $\mathbb{T}$  and assume that a fraction  $\epsilon$  in  $(0, 1)$  of the endowment is confiscated and that no borrowing is allowed after this period. On the finite horizon  $\mathbb{T}_s = \{0, 1, 2, \dots, s\}$ , instead, borrowing is permitted. We shall then take the limit over truncations in the next step of the proof. Remember that, with a single safe bond,  $v_{t+1}^i = z_t^i$  at every  $t$  in  $\mathbb{T}$ .

### C.2 Optimal plans

Given a price  $q$  in the interval  $Q$ , beginning from every contingency in period  $t$  in  $\mathbb{T}$ , we compute the indirect utility  $\bar{J}_t^i(q)$  subject to no borrowing, and no initial wealth, when a fraction  $\epsilon$  in  $(0, 1)$  of the endowment is expropriated. This indirect utility varies continuously with respect to prices  $q$  in the interval  $Q$ .

For fixed  $s$  in  $\mathbb{T}$ , we also consider a truncated program where borrowing is allowed, subject to participation, only on the finite horizon  $\mathbb{T}_s = \{0, \dots, s\}$ . In this truncated program, the endowment  $e^{i,s}$  in  $L^+$  coincides with  $e^i$  in  $L^+$  up to period  $s$  in  $\mathbb{T}$  and with the unconfiscated fraction  $(1 - \epsilon) e^i$  in  $L^+$  after period  $s$  in  $\mathbb{T}$ . At every  $t$  in  $\mathbb{T}$ , the individual is subject to participation constraint

$$U_t^i(c^i) \geq \bar{J}_t^i(q).$$

Furthermore, the holding of the bond is restricted, at every  $t$  in  $(\mathbb{T}/\mathbb{T}_s)$ , by the no borrowing constraint

$$v_t^i \geq 0.$$

Thanks to the truncation, conventional arguments show that the optimal plan varies continuously with prices, because the participation constraint is effective only over the finite horizon  $\mathbb{T}_s$ .

### C.3 The adjustment process

On the domain  $Q = [q, \bar{q}]$ , we construct a correspondence  $F : Q \rightarrow Q$  by means of the rule

$$F_t(q) = \operatorname{argmax}_{\tilde{q} \in Q} \tilde{q} \sum_{i \in I} z_t^i(q).$$

This correspondence is upper hemicontinuous with convex values on a compact domain and, thus, it admits a fixed point. We next argue by induction and prove that, at a fixed point,  $\sum_{i \in I} v_t^i \leq 0$  for every  $t$  in  $\mathbb{T}$ .

Suppose that  $\sum_{i \in I} v_t^i \leq 0$  and  $\sum_{i \in I} z_t^i > 0$ . This implies  $q_t = \bar{q}_t$ . For some individual  $i$  in  $I$  such that  $z_t^i > 0$ , as participation constraint is not binding in the following period when wealth is positive, first-order conditions imply

$$\bar{q}_t \leq \delta \mathbb{E}_t \frac{\nabla u^i(c_{t+1}^i)}{\nabla u^i(c_t^i)}.$$

Because  $c_t^i \leq \bar{\epsilon}$  by material feasibility (indeed, as  $\sum_{i \in I} v_t^i \leq 0$  and  $\sum_{i \in I} z_t^i > 0$ , material feasibility follows by adding up budget constraints) and  $c_{t+1}^i \geq \epsilon$  by individual rationality, this violates condition (C.1). Hence,  $\sum_{i \in I} z_t^i \leq 0$  and, thus,  $\sum_{i \in I} v_{t+1}^i \leq 0$ .

No borrowing after period  $s$  in  $\mathbb{T}$  implies that  $\sum_{i \in I} v_t^i = 0$  for all  $t$  in  $(\mathbb{T}/\mathbb{T}_s)$ . To complete the proof, we proceed by backward induction. Supposing that  $\sum_{i \in I} z_{t+1}^i = 0$ , we obtain that  $c_{t+1}^i \leq \bar{\epsilon}$  by material feasibility (because  $\sum_{i \in I} v_{t+1}^i \leq 0$ ). Furthermore, assuming that  $\sum_{i \in I} z_t^i < 0$ , then  $q_t = \underline{q}_t$ . By first-order conditions, along with material feasibility and individual rationality,

$$q_t \geq \delta \mathbb{E}_t \frac{\nabla u^i(c_{t+1}^i)}{\nabla u^i(c_t^i)} \geq \delta \mathbb{E}_t \frac{\nabla u^i(\bar{\epsilon})}{\nabla u^i(\epsilon)}.$$

This contradicts the lower bound given by (C.1).

### C.4 Relaxing the truncation

We now take the limit by relaxing the truncation  $s$  in  $\mathbb{T}$ . Previous steps show the existence of a truncated equilibrium prices  $q^s$  in  $Q$ , with an associated optimal consumption plan  $c^{i,s}$  in  $L^+$  for every individual  $i$  in  $I$ . For fixed  $s$  in  $\mathbb{T}$ , given any contingency in period  $t$  in  $\mathbb{T}$ , we compute the indirect utility  $J_t^{i,s}(v_t^i)$  subject to budget constraints, participation constraints and no borrowing after period  $s$  in  $\mathbb{T}$  when initial wealth is  $v_t^i$  in  $L_t$ . By convention, the value is negative infinity when constraints cannot be satisfied. For every  $t$  in  $\mathbb{T}$ , we determine  $g_t^{i,s}$  in  $L_t^+$  as

$$J_t^{i,s}(-g_t^{i,s}) = \bar{J}_t^i, \tag{C.2}$$

where the right hand-side is the indirect utility subject to no borrowing, and no initial wealth, when the fraction  $\epsilon$  in  $(0, 1)$  of the endowment is confiscated. A solution exists by continuity, as the participation constraint cannot be satisfied when the initial debt is too large and no borrowing is permitted eventually.

Also notice that  $g_t^{i,s} = 0$  for every  $t$  in  $(\mathbb{T}/\mathbb{T}_s)$ . The plan remains optimal when participation constraints are substituted by solvency constraints of the form

$$v_t^i \geq -g_t^{i,s}.$$

Thus, for the last steps, we only maintain not-too-tight solvency constraints (*i.e.*, satisfying condition (C.2)) and consider the limit with respect to  $s$  in  $\mathbb{T}$ .

Debt limits remain bounded. If not, it would be budget feasible to borrow for a large finite horizon, consuming large amount of resources, and then to revert to the plan ensuring reservation utility (see the last part of the proof of Lemma 6.3 for a similar argument). Hence, possible extracting a subsequence, consumption plans, financial plans and debt limits converge.

## C.5 Limit

As budget feasibility is satisfied in the limit, we argue by contradiction to show that the limit plan  $c^i$  in  $L^+$  is optimal subject to budget and solvency constraints. Supposing not, there exists an alternative budget feasible plan  $\hat{c}^i$  in  $L^+$ , with an associated trading plan  $\hat{z}^i$  in  $Z^i$ , yielding higher utility. By slightly contracting initial consumption and spreading this value over time by saving a fraction and freely disposing of the rest over time, we can assume that budget and solvency constraints are never binding. By discounting, for some sufficiently large  $\hat{t}$  in  $\mathbb{T}$ , we have

$$U_0^i(\hat{c}^i) + \delta^{\hat{t}+1} \mathbb{E}_0 \left( U_{\hat{t}+1}^i((1-\epsilon)e^i) - U_{\hat{t}+1}^i(\hat{c}^i) \right) > U_0^i(c^i),$$

where  $c^i$  in  $L^+$  is the dominated plan in the limit. For any sufficiently large  $s$  in  $\mathbb{T}$ , the consumption plan  $\hat{c}^i$  in  $L^+$  and the financial plan  $\hat{v}^i$  in  $L$  satisfy budget and solvency constraint at every  $t$  in  $\mathbb{T}_{\hat{t}} = \{0, \dots, \hat{t}\}$ , because budget and solvency constraints are not binding. Furthermore,  $\hat{v}_{\hat{t}+1}^i$  in  $L_{\hat{t}+1}$  satisfies  $\hat{v}_{\hat{t}+1}^i \geq -g_{\hat{t}+1}^{i,s}$ . Hence, individual  $i$  in  $I$  can implement this given plan on  $\mathbb{T}_{\hat{t}}$  and the optimal plan starting from wealth  $\hat{v}_{\hat{t}+1}^i$  in  $L_{\hat{t}+1}$  on  $(\mathbb{T}/\mathbb{T}_{\hat{t}})$ , so as to secure the utility value given by

$$\begin{aligned} U_0^i(\hat{c}^i) + \delta^{\hat{t}+1} \mathbb{E}_0 \left( J_{\hat{t}+1}^{i,s} \left( \hat{v}_{\hat{t}+1}^i \right) - U_{\hat{t}+1}^i(\hat{c}^i) \right) &\geq \\ U_0^i(\hat{c}^i) + \delta^{\hat{t}+1} \mathbb{E}_0 \left( J_{\hat{t}+1}^{i,s} \left( -g_{\hat{t}+1}^{i,s} \right) - U_{\hat{t}+1}^i(\hat{c}^i) \right) &\geq \\ U_0^i(\hat{c}^i) + \delta^{\hat{t}+1} \mathbb{E}_0 \left( U_{\hat{t}+1}^i((1-\epsilon)e^i) - U_{\hat{t}+1}^i(\hat{c}^i) \right) &> U_0^i(c^i), \end{aligned}$$

where we use the fact that the unconfiscated part of the endowment can be consumed. This shows that, for all sufficiently large  $s$  in  $\mathbb{T}$ , a utility greater than  $U_0^{i,s}(c^{i,s})$  is budget-affordable, a contradiction.

## D Dominant root

We provide a self-contained presentation of the dominant root method for simple Markov pricing kernels under incomplete markets. We begin with the

study of an abstract operator and relate our findings to the asset pricing kernel. Our analysis integrates and expands [Bloise, Polemarchakis, and Vailakis \(2017, Appendix C\)](#).

We consider a continuous operator  $\Pi : V \rightarrow V$  on some Euclidean linear space  $V$ , endowed with its canonical norm and its canonical ordering. The operator is *monotone*; that is,  $v' \geq v''$  implies  $\Pi(v') \geq \Pi(v'')$ . It is also *sublinear*; that is,  $\Pi(\lambda v) = \lambda \Pi(v)$ , for every  $\lambda$  in  $\mathbb{R}_+$ , and  $\Pi(v' + v'') \leq \Pi(v') + \Pi(v'')$ . In addition, it satisfies the property

$$v > 0 \text{ implies } \Pi(v) \gg 0. \quad (\text{D.1})$$

As usual,  $V_+$  is the positive cone of the linear space  $V$ . Monotone sublinearity is the property inherited by the pricing kernel, under no arbitrage, when markets are incomplete. Condition (D.1) obtains under strictly positive Markov transitions.

Dominant roots are defined as in our analysis in §4. The *upper dominant root*  $\rho(\Pi)$  is given by the greatest  $\rho$  in  $\mathbb{R}_+$  such that, for some non-zero  $b$  in  $V_+$ ,

$$\rho b \leq \Pi(b).$$

Analogously, the *lower dominant root*  $\gamma(\Pi)$  is given by the greatest  $\gamma$  in  $\mathbb{R}_+$  such that, for some non-zero  $b$  in  $V_+$ ,

$$\gamma b \leq -\Pi(-b).$$

The upper and the lower dominant roots capture the maximum expansion rate of the operator on the positive and on the negative cone, respectively. A simple argument establishes existence of dominant roots.

**Claim D.1** (Dominant roots). Both  $\rho(\Pi)$  and  $\gamma(\Pi)$  exist and satisfy

$$\gamma(\Pi) \leq \rho(\Pi).$$

*Proof.* Let  $\Delta$  be the unitary simplex in  $V_+$  and consider the map  $F : \Delta \rightarrow \mathbb{R}_+$  defined by

$$F(d) = \{\rho \in \mathbb{R}_+ : \rho d \leq \Pi(d)\}.$$

This is upper hemicontinuous with compact values. By the Maximum Theorem, the value function  $f(d) = \max_{\rho \in F(d)} \rho$  is upper semicontinuous. Its maximum  $\rho(\Pi) = \max_{d \in \Delta} f(d)$  is the upper dominant root. A similar argument establishes the existence of the lower dominant root. By sublinearity,

$$-\Pi(-b) \leq \Pi(b),$$

which shows that  $\gamma(\Pi) \leq \rho(\Pi)$ .  $\square$

We also show that dominant roots are uniquely identified when eigenvectors exist.

**Claim D.2** (Identification). If there is  $b$  in the interior of  $V_+$  such that, for some  $\rho$  in  $\mathbb{R}_+$ ,

$$\rho b = \Pi(b),$$

then  $\rho(\Pi) = \rho$ . Analogously, if there is  $b$  in the interior of  $V_+$  such that, for some  $\gamma$  in  $\mathbb{R}_+$ ,

$$\gamma b = -\Pi(-b),$$

then  $\gamma(\Pi) = \gamma$ .

*Proof.* As the other proof is specular, to verify the second statement, consider any non-zero  $b^*$  in  $V_+$  such that

$$\gamma(\Pi)b^* \leq -\Pi(-b^*).$$

Let  $\lambda$  in  $\mathbb{R}_+$  be the maximum value such that  $\lambda b^* \leq b$  and, at no loss of generality, assume that  $\lambda = 1$ . Monotonicity yields

$$\gamma(\Pi)b^* \leq -\Pi(-b^*) \leq -\Pi(-b) \leq \gamma b,$$

which implies  $\gamma(\Pi) \leq \gamma$ . As  $\gamma \leq \gamma(\Pi)$  by the definition of lower dominant root, the claim is proved.  $\square$

We relate dominant roots to the existence of well-defined present values. Fixing a (recursive) claim  $e$  in  $V_+$ , the upper present value is the solution to recursive equation

$$f = e + \Pi(f). \tag{D.2}$$

Analogously, the lower present value is the solution to recursive equation

$$f = e - \Pi(-f). \tag{D.3}$$

We show that present values are finite if and only if dominant roots are less than unity.

**Claim D.3** (Present values). Given a claim  $e$  in the interior of  $V_+$ , the upper (lower) present value is finite if and only if  $\rho(\Pi) < 1$  ( $\gamma(\Pi) < 1$ ).

*Proof.* We show the claim for the lower present value, as the argument is analogous in the other case. Suppose that  $\gamma(\Pi) \geq 1$  and that  $f$  in the interior of  $V_+$  solves equation (D.3). Let  $\lambda$  be the greatest value in  $\mathbb{R}_+$  such that  $\lambda b \leq f$ , where  $\gamma(\Pi)b \leq -\Pi(-b)$  and  $b$  is a non-zero element of  $V_+$ . Monotone sublinearity implies

$$\lambda b \ll e - \lambda \Pi(-b) \leq e - \Pi(-\lambda b) \leq e - \Pi(-f) \leq f,$$

a contradiction. Now assume that  $\gamma(\Pi) < 1$  and define, beginning with  $f^0 = 0$ , for every  $n$  in  $\mathbb{Z}_+$ ,

$$f^{n+1} = e - \Pi(-f^n).$$

Clearly,  $f^{n+1} \geq f^n$ . If this sequence converges, we obtain the lower present value by continuity. Otherwise, it diverges and, by linear homogeneity,

$$\frac{f^n}{\|f^n\|} \leq \frac{f^{n+1}}{\|f^n\|} = \frac{e}{\|f^n\|} - \Pi\left(-\frac{f^n}{\|f^n\|}\right).$$

Possibly extracting a converging subsequence, in the limit, for some non-zero  $b$  in  $V_+$ ,

$$b \leq -\Pi(-b),$$

which implies  $\gamma(\Pi) \geq 1$ , a contradiction.  $\square$

We are now in the condition of proving existence of dominant eigenvectors. Notice that we do not show that the lower eigenvector lies in the interior of  $V_+$ , as instead required for the identification.

**Claim D.4** (Dominant eigenvectors). There exists  $b$  in the interior of  $V_+$  such that

$$\rho(\Pi)b = \Pi(b). \quad (\text{D.4})$$

Furthermore, there exists a non-zero  $b$  in  $V_+$  such that

$$\gamma(\Pi)b = -\Pi(-b). \quad (\text{D.5})$$

*Proof.* The existence of an eigenvector satisfying (D.4) is proved in [Bloise, Polemarchakis, and Vailakis \(2017, Proposition C.1\)](#). To establish the existence of the lower eigenvector, given any  $\epsilon$  in  $(0, 1)$ , consider the perturbed operator

$$\Pi^\epsilon = \left(\frac{1-\epsilon}{\gamma(\Pi)}\right)\Pi.$$

Notice that, by linear homogeneity,  $\gamma(\Pi^\epsilon) = 1 - \epsilon$ . Fix a claim  $e$  in the interior of  $V_+$  and observe that the lower present value  $f^\epsilon$  in the interior of  $V_+$  exists for the perturbed operator (Claim D.3). Observe that  $b^\epsilon = f^\epsilon / \|f^\epsilon\|$  is in  $V_+$ , with  $\|b^\epsilon\| = 1$ , and

$$b^\epsilon = \frac{e}{\|f^\epsilon\|} - \left(\frac{1-\epsilon}{\gamma(\Pi)}\right)\Pi(-b^\epsilon).$$

Going to the limit as  $\epsilon$  in  $(0, 1)$  vanishes, possibly extracting a subsequence, we obtain the claim because the lower present value grows unboundedly and, hence,

$$\gamma(\Pi)b = -\Pi(-b),$$

thus concluding the proof.  $\square$

We apply our general analysis to a Markov pricing kernel under incomplete markets. To this purpose, we assume that uncertainty is generated by a Markov process on the finite state space  $S$ , with  $\mu_{s,\hat{s}} > 0$  being the probability of moving from state  $s$  in  $S$  into state  $\hat{s}$  in  $S$ . A finite set of securities  $J$  is traded at price  $q_s$  in  $\mathbb{R}^J$  in state  $s$  in  $S$ , each delivering a payoff  $R_{s,\hat{s}}^j$  in  $\mathbb{R}$  in state  $\hat{s}$  in  $S$  in the

following period. In state  $s$  in  $S$ , a portfolio  $z_s$  in  $\mathbb{R}^J$  can be acquired at market price

$$q_s(z_s) = \sum_{j \in J} q_s^j z_s^j,$$

yielding a contingent payoff in the following period according to

$$R_s(z_s) = \left( \sum_{j \in J} R_{s,\hat{s}}^j z_s^j \right)_{\hat{s} \in S} \in \mathbb{R}^S.$$

We assume the absence of arbitrage opportunities; that is,  $R_s(z_s) > 0$  only if  $q_s(z_s) > 0$ . Furthermore, we suppose that securities allows for a strictly positive transfer; that is,  $R_s(z_s^f) \gg 0$  for some portfolio  $z_s^f$  in  $\mathbb{R}^J$ . When this fails, the current state is disconnected from some future state.

We consider the conventional valuation operator generated by the minimum expenditure program; that is,

$$\Pi_s(v) = \min_{z_s \in \mathbb{R}^J} q_s(z_s) \quad (\text{D.6})$$

subject to

$$v \leq R_s(z_s).$$

The specular operation is given by

$$-\Pi_s(-v) = \max_{z_s \in \mathbb{R}^J} q_s(z_s) \quad (\text{D.7})$$

subject to

$$R_s(z_s) \leq v.$$

Under the stated assumptions, operator  $\Pi : \mathbb{R}^S \rightarrow \mathbb{R}^S$  is continuous, monotone and sublinear (see [LeRoy and Werner \(2014, Chapter 4\)](#)). In particular, the cost-minimizing portfolio exists under no arbitrage. We remark that condition (D.1) obtains because all Markov transitions are strictly positive. Given an arbitrage price  $q$  in  $\mathbb{R}^{J \times S}$ , we denote  $\rho(q)$  and  $\gamma(q)$  the dominant roots of the pricing operator  $\Pi : \mathbb{R}^S \rightarrow \mathbb{R}^S$ .

We compute dominant roots in the relevant case when only the risk-free (discount) bond is traded: the upper dominant root is the greatest price of the bond, whereas the lower dominant root is the least price of the bond. Hence, in such a situation, the upper (lower) dominant root is less than unity if and only if the rate of interest is always (sometimes) strictly positive.

**Claim D.5** (Safe bond only). When the risk-free bond is the only asset,

$$\rho(q) = \max_{s \in S} q_s \text{ and } \gamma(q) = \min_{s \in S} q_s.$$

*Proof.* By no arbitrage,  $q$  lies in  $\mathbb{R}_{++}^S$ . By direct inspection, let  $b$  in  $\mathbb{R}_{++}^S$  be given by  $b_s = q_s$  at every  $s$  in  $S$ . To satisfy the constraint in (D.6), it is necessary

to hold at least a quantity  $\max_{\hat{s} \in S} q_{\hat{s}}$  of the risk-free bond (with unitary payoff). Thus,

$$\Pi_s(b) = \left( \max_{\hat{s} \in S} q_{\hat{s}} \right) q_s = \left( \max_{\hat{s} \in S} q_{\hat{s}} \right) b_s = \rho(q) b_s.$$

Similarly, to satisfy the reverse constraint in (D.7), it is necessary to hold no more than quantity  $\min_{\hat{s} \in S} q_{\hat{s}}$  of the risk-free bond. Thus,

$$-\Pi_s(-b) = \left( \min_{\hat{s} \in S} q_{\hat{s}} \right) q_s = \left( \min_{\hat{s} \in S} q_{\hat{s}} \right) b_s = \gamma(q) b_s.$$

It may well be true that the upper dominant root is larger than unity,  $\rho(q) > 1$ , because the rate of interest is negative,  $q_s > 1$ , in some state  $s$  in  $S$ .  $\square$

To conclude, we show continuity of valuation as asset prices vary.

**Claim D.6** (Continuity). For given  $b$  in  $\mathbb{R}^S$ , at every  $s$  in  $S$ , the minimum-cost  $\Pi_s(b, q)$  is continuous in (arbitrage-free) security prices  $q$  in  $\mathbb{R}^{J \times S}$ .

*Proof.* Pick a sequence of prices  $(q^n)_{n \in \mathbb{N}}$  in  $\mathbb{R}^{J \times S}$  converging to  $q$  in  $\mathbb{R}^{J \times S}$ . Letting  $z_s$  in  $\mathbb{R}^J$  be a minimum-cost portfolio in the limit, we have

$$\Pi_s^n(b) - \Pi_s(b) \leq q_s^n(z_s) - q_s(z_s).$$

It follows that

$$\limsup_{n \rightarrow \infty} \Pi_s^n(b) \leq \Pi_s(b).$$

In order to obtain a contradiction, assume that

$$\liminf_{n \rightarrow \infty} \Pi_s^n(b) < \Pi_s(b).$$

As the sequence  $(\Pi_s^n(b))_{n \in \mathbb{N}}$  in  $\mathbb{R}$  is bounded, we can assume that it converges at no loss of generality. Letting  $z_s^n$  in  $\mathbb{R}^J$  be a minimum-cost portfolio at  $n$  in  $\mathbb{N}$ , we have

$$q_s^n(z_s^n) - q_s(z_s^n) \leq \Pi_s^n(b) - \Pi_s(b).$$

Notice that, as the pricing kernel is linear, we can suppose that the there are no redundant securities, or equivalently that portfolios are taken in the quotient space. If the sequence  $(z_s^n)_{n \in \mathbb{N}}$  in  $\mathbb{R}^J$  remains bounded, we can assume that it converges to  $z_s$  in  $\mathbb{R}^J$  at no loss of generality. This yields

$$0 \leq \lim_{n \rightarrow \infty} q_s^n(z_s^n) - q_s(z_s^n) \leq \lim_{n \rightarrow \infty} \Pi_s^n(b) - \Pi_s(b) < 0,$$

a contradiction. Otherwise, the sequence  $(\tilde{z}_s^n)_{n \in \mathbb{N}}$  in  $\mathbb{R}^J$  is bounded, where

$$\tilde{z}_s^n = \frac{1}{\|z_s^n\|} z_s^n.$$

Assuming convergence to  $\tilde{z}_s$  in  $\mathbb{R}^J$  at no loss of generality, we obtain

$$0 \leq q_s(\tilde{z}_s) = \lim_{n \rightarrow \infty} q_s^n(\tilde{z}_s^n) \leq \lim_{n \rightarrow \infty} \frac{1}{\|z_s^n\|} \Pi_s^n(b) = 0$$

and, at every  $\hat{s}$  in  $S$ ,

$$0 = \lim_{n \rightarrow \infty} \frac{1}{\|z_s^n\|} d_{\hat{s}} \leq \lim_{n \rightarrow \infty} R_{s, \hat{s}}(\tilde{z}_s^n) = R_{s, \hat{s}}(\tilde{z}_s).$$

No arbitrage pricing so implies that  $R_{s, \hat{s}}(\tilde{z}_s) = 0$  for every  $\hat{s}$  in  $S$ . By no redundancies,  $\tilde{z}_s$  is the zero portfolio in  $\mathbb{R}^J$ , which contradicts the fact that  $\|\tilde{z}_s\| = 1$ .  $\square$
